ARMATURE INDUCTANCE. — Each coil of the armature carries a current flowing in one direction as it travels from a positive brush to a negative brush and in the opposite direction as the coil travels from a negative to a positive brush. Thus the direction of the current in each coil reverses during the time the commutator bars to which the coil is connected pass under the brush. To reverse the current in any circuit it is necessary to take out the energy stored up in the form of magnetic flux linked with the circuit, and put back an equal amount represented by a flux in the opposite direction. In doing this there is induced in the circuit a voltage which is proportional to the time

rate of change of the flux and which opposes any change in the value of the current. This voltage is the e.m.f. of self-inductance of the coil.

Methods of Improving Commutation. — To minimize the voltage of self-inductance it is necessary to keep the number of ampere-turns in each coil as low as possible and to cause the reversal to take place as slowly as possible. It is possible to neutralize the voltage of self-inductance by introducing an opposing voltage, which is accomplished in practical machines by giving the brushes a forward lead or by using interpoles.

Forward Lead of Brushes. — The brushes are moved in the direction of rotation in a generator (opposite direction in a motor) away from the true neutral until the coil undergoing reversal is moving in a flux coming from an adjacent pole tip of such a density that it induces by rotation in that particular coil a voltage that opposes and neutralizes the voltage of self-inductance.

Effect of Interpoles on Commutation. — Interpoles or commutating poles are placed between the main poles over the neutral space. These poles are excited by the load current until they give a flux of the proper direction and value to induce the desired neutralizing voltage. (*See also above under Armature Reaction.*)

Increasing Resistance in Path of Short-circuit Current also aids commutation. This changes the time constant of this circuit, that is, some of the stored energy of the magnetism is dissipated in I^2R loss in this resistance instead of in sparking at the brush. The usual method of accomplishing this is to use carbon brushes which have a higher resistance of contact than metal brushes. Another method is to introduce a high resistance in the connection between the winding and the commutator segment.

DESIGN. — The steps in the systematic procedure in the design of a d-c. machine of given voltage and power rating are given below. Simplex windings are assumed.

1. Statement of problem.
2. Suitable speed.
3. Number of poles.
4. Diameter and length of armature.
5. Length of air gap.
6. Number and size of slots.
7. Total flux, preliminary.
8. Number of turns on armature, preliminary.
9. Armature reaction, ampere-turns.
10. Number of conductors per slot.
11. Form of armature winding.
12. Size of armature conductors.
13. Exact size of slots.
14. Armature resistance and heating.
15. Design of commutator and brushes.
16. Reactance voltage.
17. Exact value of flux.
18. Cross-section of magnetic path; usual flux densities.
19. Excitation; calculation of magnetic circuit.
20. Stability factor.
21. Armature reaction or interference.
22. Field winding, series, shunt.
23. Interpoles or commutating poles.

The performance of the machine should then be calculated from the preliminary design to determine whether the design meets the imposed conditions

and such modifications as are necessary should then be made. The steps in calculating the performance are the calculations of:

24. Core-loss.
25. Friction.
26. Excitation loss.
27. Armature circuit loss.
28. Efficiency.
29. Regulation.
30. Heating.

Symbols. — The following notation is employed uniformly throughout this article; other symbols, and the same symbols with primes or subscripts, are defined in the paragraphs in which they are used.

(AR) = armature reaction ampere-turns per pole.
B = flux density in air gap, lines per sq. inch.
b = number of coil sides in series per slot.
C = total field ampere-turns per pole.
c = number of conductors per slot.
D = outside diameter of armature, in inches.
E = terminal armature voltage.
e = reactance voltage of short-circuited coil.
$f = \frac{pN}{120}$ = frequency of voltage induced in armature.
I = full-load line current, in amperes.
L = length of armature, in inches.
m = number of parallel paths between brushes.
N = revolutions per minute.
P = power output in kilowatts in case of generator; input in case of motor.
p = number of poles.
$\mathcal{P}$ = permeance of local magnetic path of short-circuited coil.
q = cross-section of one armature conductor, in square inches.
R_a = effective resistance of armature between brushes, in ohms.
$S = \frac{Z}{2m}$ = number of turns in series between brushes.
s = total number of slots.
V = peripheral velocity of armature in feet per minute.
V_c = peripheral velocity of commutator in feet per minute.
Z = total number of coil sides.
$z = \frac{Z}{p} = \frac{bs}{p}$ = average pitch of end connections.
ν = leakage coefficient.
$\rho = \frac{\text{pole arc}}{\text{pole pitch}}$; pole pitch is the arc from pole center to center of adjacent pole, measured at air gap; pole arc is the arc covered by the pole face.
σ = ampere-conductors per inch of armature periphery.
ϕ = total useful flux per pole.

1. Statement of Problem. — The rating in kilowatts or horse-power and the voltage are always given. The current and speed may or may not be given. The line current at full load is found as follows:

For a generator $$I = \frac{1000\,P}{E}.$$

For a motor $$I = \frac{746 \times (\text{Horse-powet})}{E \times (\text{Efficiency})}.$$

The proper efficiency to assume may be taken from the table of usual values given below in section 28.

2. Suitable Speed (N).—Machines are classified in commercial practice as high speed, moderate speed and low speed. The proper speed for a machine of a given size for each class is given in the curves in the section below on *Cost, Weight, and Speed.*

3. Number of Poles (p) depends upon the size, speed and character of the machine. There is, however, much variation depending upon specific conditions. Reasonable arrangements are indicated in the accompanying table.

Kw. rating	Number of poles		
	High speed	Moderate speed	Low speed
0–10	2	4	4
10–50	4	4	4
50–100	4	4–6	6
100–300	6	6	8
300–500	6	8	10
500 and greater	..	..	12 and more

4. Diameter and Length of Armature are related by the following formula:

$$D^2L = \frac{550\,P \times 10^9}{\sigma \rho BN}.$$

Usual Values of the Constants in the above formula are:

Magnetic Density in Air Gap (B) has values from 40,000 lines per square inch in small machines, 55,000 in medium and 70,000 in large machines. In general, the density in the air gap is taken the same as the density at the pole face.

Ampere-Conductors per Inch of Periphery, or the Specific Loading (σ) is the product of the total conductors around the armature times the current in each, divided by the periphery of the armature. The usual values for σ are given in accompanying table.

Kw. rating	σ-amp.-cond. per inch of periphery	
	For continuous rating	For intermittent rating
0–150	250–400	700
150–400	400–600	1000
400 and greater	600–900	1200

Ratio of Pole Arc to Pole Pitch (ρ) varies from 0.6 to 0.85 with an average value of 0.7.

Determination of D and L.—Having found D^2L the two factors may be separated by two methods. Assuming a square pole face (a desirable proportion for economy of armature and field copper), then

$$L = \frac{\pi \rho D}{p},$$

and substituting in D^2L we can solve for D.

Another method of determining separate values for D and L is by a consideration of the peripheral speed. The peripheral speed is fairly uniform in d-c. machines, having values of from 3000 to 5000 feet per minute. Assume an average value near 4000. The diameter of armature is given by the formula

$$D = \frac{(\text{Peripheral speed}) \times 12}{\pi N}.$$

5. Length of Air Gap in inches for a given diameter has a value given approximately by the table in the next paragraph. This gives a good value

for preliminary work but it may be found advisable to change it later in the design.

6. Number and Size of Armature Slots. — A rough approximation to practice gives the number of slots as four times the diameter in inches. General practice is shown in the table.

D = arm. diam., in.	Air gap, in.	No. of slots	Depth of slots, in.
5	0.08	25- 40	0.6
10	0.10	30- 60	0.75
15	0.12	40- 80	1.00
20	0.125	60-100	1.25
30	0.15	80-150	1.50
50	0.19	100-200	1.75
100	0.25	150-300	2.50
150	0.35	200-400	3.25

7. Total Flux in the Armature (ϕ) is fixed by the assumed gap density B and the length L and diameter D of the armature:

$$\phi = \frac{\pi \rho L D B}{p}.$$

8. Number of Turns in Series (S) between brushes is

$$S = \frac{E \times 10^8}{4 f \phi}.$$

9. Armature Reaction Ampere-Turns per Pole are

$$(AR) = \frac{IS}{p}.$$

The armature reaction ampere-turns per pole (AR) should not exceed certain values and should properly check as explained in the accompanying table.

If the (AR) comes out higher than advisable it is reduced by increasing the value of the flux by increasing either B, L or D.

Kw. rating	Armature reactive ampere turns per pole (AR)
0-100	1500-3500
100-300	3500-6000
300-500	6000-8000

10. Number of Conductors per Slot (c). — If s is the total number of slots on the armature, the proper number of conductors per slot (c) must fulfill two conditions which are sometimes antagonistic and therefore the solution is a compromise.

For a multiple-drum winding:

$$c = \frac{\pi \alpha p D}{Is} \quad \text{and} \quad c = \frac{2pS}{s}.$$

For a series-drum winding:

$$c = \frac{2\pi\sigma D}{Is} \quad \text{and} \quad c = \frac{4S}{s}.$$

c must be an even number and give a number of conductors which can be conveniently arranged in a slot having a depth of from 3 to 4 times its width. If c comes out very large for a multiple winding we then choose a series winding.

11. Form of Armature Winding (for general discussion of forms of windings see above).

Multiple-drum Winding. — If the number of conductors per slot (c) indicates the desirability of a multiple-drum winding, we choose an arrangement having an even number of coil sides per slot and assume the conductors per slot at a value the nearest multiple of the coil sides per slot, thus grouping the conductors into coils.

Series-drum Winding. — If a series-drum winding is indicated:

For a four-pole machine choose a number of conductors per slot (c) divisible by 6 and a number of slots (s) in the series 29, 33, 37, etc., endeavoring to obtain

that value of $\frac{sc}{4}$ that comes nearest to our preliminary value of S, the number of turns in series between brushes. Or for a four-pole machine choose a number of conductors divisible by 10 and a number of slots in the series 27, 31, 35, that gives a value of $\frac{sc}{4}$ the nearest the preliminary value of S.

For a six-pole machine choose a value of c divisible by 4 and a number of slots (s) in the series 26, 32, 38, that gives a value of $\frac{sc}{4}$ nearest the desired value of S.

The preceding values of s give the best winding arrangement but there are other combinations giving unequal front and back pitches and longer connections.

Revised Value of Turns in Series (S). — Having chosen arbitrarily values for s and c to fit the form of winding desired we must revise our preliminary assumption for the turns in series, S, to accord with the actual winding. Thus for a multiple drum $S = \frac{sc}{2p}$, and for a series drum $S = \frac{sc}{4}$.

12. Size of Armature Conductors.— The current in each conductor is equal to the line current I divided by the number of poles in a multiple-drum winding, and to $I/2$ in a series-drum winding of the simple type. The cross-section of each conductor is equal to the current per conductor divided by the allowable amperes per square inch, which varies from 3000 in small machines and 2000 in intermediate size machines to 1500 in large machines.

13. Exact Size of Slots, Slot Factor. — The total number of slots is definitely set by the style of winding. The maximum allowable depth depends upon the diameter of the armature. The width of each slot should be from 0.4 to 0.6 of the pitch of the slots, which is the quotient of the periphery of the armature divided by the number of slots. The ratio of the total cross-section of copper in a slot to the cross-section of the slot is known as the slot factor and has more or less consistent values.

Kw. rating	Slot factor	
	For 125 volts	For 500 volts
0– 10	0.28	0.20
10– 50	0.35	0.25
50– 100	0.40	0.30
100– 400	0.50	0.40
400–1000	0.60	0.50

The actual dimensions of the slots are found by adding to the width and depth of the cotton covered conductors, suitably arranged, an allowance for the coil and slot insulation. The allowances in the accompanying table are for voltages of 500 and less.

Type of slot	No. of bars or coil-sides per slot	Allowance for coil and slot insulation, in.	
		Width	Depth.
Open	2	0.09	0.30
Open	4	0.14	0.35
Open	6	0.15	0.35
Partly closed	4	0.15	0.40

14. Armature Resistance and Heating. — The mean length of turn is obtained from a drawing or is roughly estimated as

$$l = 2L + \frac{10D}{p}.$$

The equivalent resistance of the armature from brush to brush is

$$R_a = \frac{0.0093\,Sl}{12{,}000\,qm}.$$

The voltage drop in the armature is R_aI.

The loss in armature copper is R_aI^2.

The rise in temperature of the copper in ° C. is given approximately for preliminary purposes by

$$T_c = \frac{100\,R_aI^2}{(a+b)\,ls},$$

where

a = width of coils in slot, in inches.
b = depth of coils in slot, in inches.

15. Design of Commutator and Brushes. — The diameter of the commutator must be less than the diameter of the armature. The peripheral speed should be about 3000 feet per minute and should not exceed 4000 unless a special construction is used. The number of segments should be such that the average volts per bar should be less than 15.

$$\text{Volts per bar} = \frac{(\text{Rated voltage}) \times (\text{Poles})}{\text{Number of segments}}.$$

To avoid a weak construction the pitch of segments should not be less than 0.20 inch. Of this amount about 30 mils is occupied by insulation.

Dimensions of Brushes. — The width of the brushes is limited by the number of commutator segments which it is permissible to cover and the width of these segments. The number of segments covered is limited by the reactance voltage, as explained below. In general, the width of the brushes is from 2 to 3 times the pitch of segments. The area of the brush surface is such as to allow from 40 to 50 amperes per square inch of brush contact surface at full load. This surface is distributed equally over a number of studs equal to one-half the number of poles with a multiple-wound armature and may be all on one stud or disposed at pleasure with a series-wound armature.

Total Length of Commutator. — The total length of brushes per stud or the active length of the commutator is

$$l_c = \frac{2 \times (\text{Total brush surface})}{(\text{Width of brushes}) \times (\text{No. of studs})}.$$

The total length of commutator is greater than this by about 0.5 inch to allow for clearances between brushes and at the ends. It is also customary to allow an extra space at the end of the commutator for insulation to prevent creepage. Commutators in general have a gross superficial area of from 0.67 to 1.0 square inch per ampere of total current.

Resistance of Brushes and Brush Contact is a variable quantity. Some designers allow 2 volts total drop in positive and negative brushes under all conditions of load.

Another method is to use the values for the resistance per square inch of each brush and brush contact as given in the accompanying table.

Peripheral speed, ft. per min.	Res. of each brush, ohm		
	20 amp. per sq. in.	40 amp. per sq. in.	60 amp. per sq. in.
2400	0.035	0.024	0.02
2800	0.036	0.024	0.021
3200	0.037	0.025	0.022
3600	0.038	0.026	0.023

Friction of Brushes on Commutator. — The value of this loss is

$$\text{Friction in watts} = \frac{(\text{No. of brushes}) \times (\text{Pressure per brush}) \times V_c \times k}{45},$$

where

V_c = peripheral speed of commutator, feet per minute.
k = coefficient of friction = 0.2 to 0.3.

The usual value of pressure on the brushes is from 1.5 to 2 pounds per square inch of contact surface.

Rise in Temperature of Commutator is

$$T = t \times \frac{(\text{Brush } I^2R) + (\text{Brush friction})}{\text{Surface of commutator}}$$

where t has the value indicated in the accompanying table; t is the temperature rise in °C. for a total commutator loss of 1 watt per sq. in.

Peripheral speed of commutator, ft. per min.	Value of t.
2000	30
3000	20
4000	10

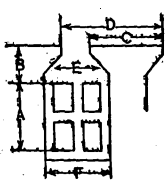

Fig. 14. Slot Diagram

16. Reactance Voltage. — The permeance of the local magnetic path surrounding each coil is

$$\mathcal{P} = 2\left(\frac{A}{3F} + \frac{B}{E} + \frac{C}{D}\right)(l_1 + 0.1\, l_2),$$

where the distances, expressed in inches (see Fig. 14), are as follows:

A = from top of upper conductor to bottom of lower,
B = from top of upper conductor to surface of armature,
C = width of tooth at face,
D = pitch of slots at surface,

E = mean width of wedge portion of slot,
F = width of slot proper,
l_1 = length of embedded portion of a coil side,
l_2 = length of free portion of coil side.

The coefficient 0.1 for l_2 allows for the fact that the flux surrounding the end connections is about one-tenth as great as that in the embedded portion of the coil.

The flux set up by each ampere flowing per coil is $3.2\,\mathcal{P}C$, where C is the number of conductors undergoing commutation simultaneously.

$$C = (\text{Turns per coil}) \times \frac{(\text{Brush width}) \times k}{\text{Segment pitch}}.$$

If the brush covers two segments there are 2 coils undergoing commutation at that brush and 2 under the brush of opposite polarity. All these coils will have conductors lying in the same slot if the windings have full or normal pitch. Hence $k = 2$, for full pitch, less for other pitches.

The inductance of a short-circuited coil is

$$L_c = 3.2\,\mathcal{P}Ct \times 10^{-8} \text{ henries},$$

where

t = turns in series short-circuited by the brush
= $k_2 \times$ (turns per coil)
k_2 = 1 for all multiple drum-windings
= number of poles in series in armature for series drum-windings.

The reactance voltage is then

$$e = 2\pi f_c L_c I_c,$$

where

$I_c = \dfrac{I}{m}$ = current per circuit,

f_c = frequency of commutation $= \dfrac{12\,V_c}{120 \times (\text{Brush width in inches})}$,

V_c = peripheral speed of commutator, feet per minute.

17. **Exact Value of Flux Leakage Coefficient** (v). — The exact number of turns was determined under *Form of Armature Winding*, section 11, above. The useful flux in the armature must then be

$$\phi = \frac{(E + R_a I) \times 10^8}{4fS}.$$

The flux in the pole or magnet core and the field yoke is greater than this, due to the leakage between poles. The ratio of the flux in the field to that in the armature is known as the leakage coefficient. It may be easily determined for each particular machine by the method given in the article on *Generators, Alternating-Current;* or if ample margin in the strength of field is always allowed it may be assumed without great error.

Rating in kw.	Leakage coefficient
2.5	1.2 –1.5
5	1.18–1.4
10	1.16–1.35
25	1.15–1.30
50	1.14–1.28
100	1.12–1.20
500	1.08–1.15

18. **Cross-Section of Magnetic Path. — Usual Flux Densities.** — Usual magnetic densities for determining the proportions of the magnetic circuit are given in the accompanying table.

Part	Material	Lines per sq. in.
Field yoke	Steel	70,000–100,000
Field yoke	Cast iron	35,000– 70,000
Pole core	Steel	70,000–100,000
Air gap	Air	40,000– 70,000
Armature teeth	Steel laminations	90,000–125,000
Armature core	Steel laminations	60,000– 90,000

The proper cross-section of each part is found by dividing the flux in that part by an assumed density. (*See also following paragraph.*) In most cases one dimension, as the length along the shaft, is known and the other is thus fixed.

19. Excitation. — Calculation of Magnetic Circuit. — It is advisable to calculate the densities and excitation for a value of flux corresponding to $E + R_a I$ at the speed at full load, as this is the most important condition. It is common practice to assume a loss of voltage of 5 per cent at full load instead of accurately predetermining the value.

Values of Flux in Different Parts of Magnetic Circuit. — In the armature teeth and air gap the total flux is equal to the calculated value of the useful flux. In the armature core the flux divides and we have one-half the useful flux in each branch. The field flux or flux in pole cores is greater than the useful flux and is equal to the useful flux multiplied by the leakage coefficient (ν). (*See section* 17.) In the yoke the flux divides and each branch contains one-half as much as the pole core.

Ampere-Turns. — The number of ampere-turns required for excitation is best calculated by the assistance of a tabulation like the following, in which the symbols refer to the dimensions shown in Fig. 15.

1	2	3	4	5	6	7
Part	Flux	Cross-Section	Flux density	Amp.-turns per in.	Length of path	No load amp.-turns per pole
Field yoke....	$\frac{\nu\phi}{2}$	de	......	....	i	......
Pole core......	$\nu\phi$	$0.785 f^2$ or fb	......	....	c	......
Air gap........	ϕ	aL_p	......	$0.313\ B$	g	......
Arm. teeth....	ϕ	$Tt_0\ l_i$	......	....	n	......
Arm. core.....	$\frac{\phi}{2}$	hl_i	......	....	k	......

Net ampere-turns for flux: .....

The dimensions in column 3 can be taken directly from a sketch similar to Fig. 15. If the pole is circular its area is $0.785\ f^2$ and if it is square its cross-

section is fb. The length of pole shoe L_p is usually about 0.5 inch less than L, the length of armature core.

The effective cross-section of the armature teeth is found as follows: At any given time only a portion of the teeth are carrying flux. These are known as the teeth under one pole, T, and are slightly greater than those actually under the pole, on account of the tendency of the flux to spread.

$$T = \frac{a + 2g}{p_1},$$

where a = pole arc, g = length of gap, p_1 = pitch of slots at face.

The effective or equivalent cross-section of the teeth is not that which gives the average density but that which gives the mean excitation required and is

$$\frac{(t_1 + 2t_2)}{3} l_i = t_0 l_i.$$

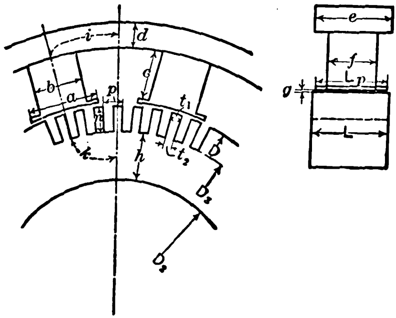

Fig. 15. Dimensions of Magnetic Circuit

The factor l_i is introduced to give the effective length of iron, excluding that space occupied by the insulation between laminations.

$$l_i = 0.9 \times (L - \text{space of air ducts}).$$

Thus the equivalent cross-section of armature teeth = $T t_0 l_i$.

Column 4 is the flux (column 2) divided by the cross-section (column 3).

Column 5 contains the ampere-turns per inch which are to be taken from saturation curves for the respective materials as given in the article on *Magnetic Properties of Iron.* The magnetizing force for a one-inch gap is always 0.313 B.

Column 6 gives the lengths of the respective paths as shown on Fig. 15.

Column 7 contains the ampere-turns required for each part of the path and is obtained by multiplying the values in column 5 by the respective lengths in column 6. The sum of all values in column 7 is the excitation in ampere-turns required on *each pole* of the field to establish the necessary flux in the machine. With no current flowing in the armature this would give a voltage about 5 per cent greater than the rated voltage of the machine. See section 21 below for compensation for armature reaction.

20. **Stability Factor.**—It is necessary at this point in the design to check the relations to see if the machine is liable to be unstable or require an excessive shift of the brushes. If interpoles are to be used this is not important, but if interpoles are not to be used certain conditions must be fulfilled. The criterion of these conditions is the "stability factor" which is the quotient of the field ampere-turns required for gap and teeth divided by the armature ampere-turns beneath the pole.

The ampere-turns beneath the pole are equal to

$$\frac{(\text{Armature reaction ampere-turns}) \times (\text{Pole arc})}{\text{Pole pitch}}.$$

The conditions to be filled are that at maximum current in the armature the armature ampere-turns beneath the pole shall not exceed the field ampere-turns required for gap and teeth. This is covered by the custom of making the stability

factor at full load have a value of from 1.3 to 1.5 in generators and 1.5 to 3 in motors.

21. Armature Reaction or Interference.—The current in the armature conductors sets up a magnetomotive force which reacts on the magnetomotive force of the field coils and prevents them from setting up as much flux as when there is no current in the armature. It is, therefore, necessary to have the field strength at any load greater than at no load by an amount sufficient to overcome or neutralize the armature reaction, or to provide special auxiliary poles for the purpose. There are four methods of estimating the effect of armature interference and overcoming it.

(*a*) It is common practice in the manufacture of d-c. machines to provide a field coil of such ample capacity that it is sure to be more than sufficient to overcome armature interference and set up the flux desired. This field is then adjusted in practice by putting an adjustable resistance in series with the shunt field and a suitable resistance in multiple with the series field. For this practice it is usual to provide a total number of field ampere-turns per pole (C) equal to the net ampere-turns per pole at full load required for flux, as calculated under item No. 19, plus a number of field ampere-turns equal to 40 per cent of the armature reaction ampere-turns as calculated under item No. 9.

(*b*) The effect of armature reaction is divided into back ampere-turns and cross ampere-turns. The excitation ampere-turns to overcome the back ampere-turns (caused by shifting the brushes) is

$$A' = \frac{(\text{Armature reaction}) \times (\text{Brush shift in segments}) \times p}{\text{Total commutator segments}}.$$

The excitation to overcome the effect of the cross ampere-turns depends upon many variables but in machines designed in accordance with standard practice it bears a fairly uniform relation to the cross ampere-turns, depending upon the value of the ampere-turns in gap and teeth, as follows:

Cross ampere-turns = (armature reaction ampere-turns) − (back ampere-turns).

Field ampere-turns to compensate for cross ampere-turns is then $B' = K \times$ (cross ampere-turns).

Where K has values as shown in Fig. 16 (*given by Cramp, see Bibliography*). Thus the total field ampere-turns at full load is then equal to

$$C = (\text{Net ampere-turns for flux, section 19}) + A' + B'.$$

(*c*) It is possible by working with the saturation curve of the machine to actually determine the effect of the cross ampere-turns on the saturation in the teeth and pole face. This method is too elaborate and complicated to be discussed here and is of more value for educational than for practical purposes. It is discussed very fully in the books by S. P. Thompson and E. Arnold (*see Bibliography, below*).

(*d*) Interpoles may be used as described in section 23.

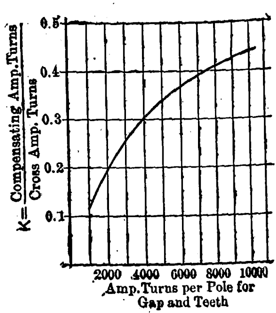

Fig. 16. Constant for Cross Ampere-turns

Excitation for Various Loads.—At no load the excitation required would be only that necessary to produce a flux corresponding to the rated terminal voltage. At any load corresponding to a current I the excitation in

ampere-turns must be equal to the sum of: (1) that required to produce a flux corresponding to $E + RI$, where R is the total resistance of the armature between brushes, the brush resistance and the resistance of the series field; (2) that required to overcome the back ampere-turns caused by I, and (3) that required to overcome the cross ampere-turns due to I. The process of calculation indicated in sections 19, 20 and 21 for full-load conditions is, therefore, repeated for other load conditions.

22. Field Winding. — If the machine has a series field this should be laid out first, since the shunt-field coils are sometimes placed outside of, and concentric with, the series-field coils.

Series Field. — For a compound-wound machine the ampere-turns required in the series field are equal to the difference between the full-load ampere-turns and the no-load ampere-turns. As it is usual to shunt about 25 per cent of the current through a shunt resistance the number of series turns per pole for each coil is

$$t_1 = \frac{\text{Ampere-turns required}}{0.75 \times \text{Load current}}.$$

The cross-section of each turn in square inches is taken equal to the full-load current divided by 1000.

This winding is usually wound in copper strap like a ribbon, the width being equal to the total length of field spool if it is wound under the shunt winding, or is arbitrarily chosen if the two coils are placed side by side. The thickness of each turn is the quotient of the cross-section divided by the width.

The coils are wound with an extra odd half turn to facilitate connection. Thus the depth of winding is

$$(\text{Thickness} + 0.016 \text{ for insulation})\ (t_1 + 1).$$

Allowance for a layer of insulation inside and outside adds about 0.375 inch to the depth of winding.

The mean length of turn l_f' is (see Fig. 16):

For square pole $l_f' =$ (periphery of pole) + 4 (depth of winding).

For round pole $l_f' = \pi\ (f +$ depth of winding).

The resistance is

$$r_1 = \frac{0.0093\, t_1 l_f'}{12{,}000\, q_1},$$

where q_1 is the cross-section of a turn.

The total drop in voltage in the series field is $0.75\, r_1 I$ which should be between 0.5 per cent and 1 per cent of the rated voltage.

Shunt Field. — The shunt field is required to give a certain number of ampere-turns, usually equal to the no-load ampere-turns. Let this number of ampere-turns per pole be F. At 1000 amperes per square inch the cross-section of copper in a coil would be $F/1000$. The total cross-section of the coil, including insulation, is determined by means of the space factor f'. Then the cross-section of the coil $= \dfrac{F}{1000 f'}$, where f' has a value of 0.5 if No. 18 B. & S. wire is used, 0.55 for No. 12, 0.60 for No. 6, and from 0.6 to 0.8 where copper ribbon is used. Where very small wires are used f' becomes as small as 0.25 (*see article on Electromagnet Windings*).

The depth of winding will be

$$b_2 = \frac{F}{1000 f' c_2},$$

where $c_2 =$ length of coil (*see Fig. 17*).

The superficial area will be (see Fig. 17) $A_2 = 2\,(f + b + 4\,b_2)c_2$.

The rise in temperature in ° C. of the coil will be from 60° to 80° per watt per square inch of A_2; thus for 40° rise on the spool the watts (w_2) per spool should be from $0.5\,A_2$ to $0.6\,A_2$ depending upon the ventilating effect of the armature.

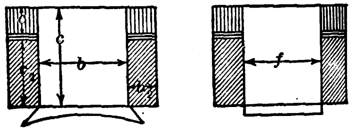

Fig. 17. Dimensions of Field Coils

Voltage per spool under normal conditions, allowing 25 per cent to spare for rheostat, will be

$$e_2 = \frac{0.75\,E}{p}.$$

$$\text{Current in shunt field} = i = \frac{w_2}{e_2}.$$

$$\text{Turns per spool} = t_2 = \frac{F}{i}.$$

$$\text{Mean length of turn, in in.} = l_f = 2\,(f + b + 2\,b_2) \text{ or } = \pi\,(f + b_2).$$

$$\text{Resistance per spool} = r_2 = \frac{e_2}{i}.$$

Cross-section of conductor in sq. in. =

$$q_2 = \frac{0.0093\,l_f t_2}{12{,}000\,r_2}.$$

The size of wire having a cross-section as nearly equal to q_2 as possible is chosen and arranged in layers. Single cotton-covered wire is used. The number of turns per layer is found by dividing c_2 by the outside diameter of the single cotton-covered wire.

Certain allowances must be made for the thickness of the spool and of the collars or flanges.

After these details of arrangement are settled it is advisable to recalculate the mean length of turn, the resistance, and the heating to be sure that the practical details have not interfered with the preliminary assumptions of watts per square inch.

23. **Interpoles or Commutating Poles** are used where either the armature reaction or the reactance voltage is very great. If the armature reaction at full load is greater than 80 per cent of the field ampere-turns at no load, then interpoles should be considered. If the reactance voltage is greater than 2.5 volts, interpoles should be considered.

The design of the interpoles may be roughly made in accordance with the practice in some of the large companies by making its width equal to the width of two slots and two teeth, and proportioning the winding to have 1.4 times as many ampere-turns as the armature reaction ampere-turns (AR). The axial length of the pole is frequently less than that of the armature, the gap density should be about 40,000 and the iron or steel of the pole should not be saturated when 1.5 times the full-load current is flowing through its windings.

In practice a shunt having inductance is connected across the terminals of the interpole winding and adjusted for sparkless commutation. When the interpoles are used on a compound-wound generator it is possible to decrease the strength of the series coils to such a value as will produce the proper flux for the desired $E + rI$, letting the interpoles take care of the armature reaction. Series coils having 20 per cent as many ampere-turns as the armature will be satisfactory.

Exact Design of Interpoles. — A more exact method starts with the value of the reactance voltage, e, and an assumed density in the air gap of $B_1 = 40{,}000$. The axial length of the interpole is then

$$L_1 = \frac{10^8 \times e}{kB_1 v_a},$$

where

v_a = the peripheral velocity of armature in inches per second,
k = number of inductors in series in short-circuited coil = $2\,t$ (*see formula for reactance voltage, section 16*).

The width (a_1) of pole at face is made equal to or a little greater than twice the pitch of armature slots. The flux per pole in gap is $\phi_1 = B_1L_1a_1$.

The leakage coefficient is higher for interpoles than for the main poles and is in the neighborhood of 1.6 to 1.8.

The magnetic density is kept low in the pole core so that there will be margin for overload.

The necessary exciting ampere-turns to force this flux through the gap and to take care of the leakage and increased densities in the field and armature core are calculated. Let this value be A''.

Let the armature reaction ampere-turns per pole be B''.

Then the total ampere-turns on the interpoles should be $A'' + B''$.

The number of turns per pole is $(A'' + B'')$ divided by the full-load current of the machine, and the winding itself is laid out in the manner employed in laying out the series field.

PREDETERMINATION OF PERFORMANCE FROM DESIGN. — The steps involved in predetermining what will be the performance of a given design are the following:

24. **Core-Loss.** — The core-loss consists of hysteresis and eddy current losses in the armature teeth and core. It is best calculated by taking from the curves in the article on *Magnetic Properties of Iron* the hysteresis loss per cubic inch at one cycle per second for the proper density and the eddy loss per cubic inch at one cycle per second for the proper density and thickness of sheet. These values are substituted in the following formulæ.

Total loss in core $= V_cC_hf + V_cC_ef^2$,
Total loss in teeth $= V_tC_hf + V_tC_ef^2$,

where

V_c and V_t = volume in cubic inches of core and teeth respectively,
C_h = constant from hysteresis loss curve for proper density,
C_e = constant from eddy loss curve for proper density, and thickness of sheet.
f = frequency.

A rough value for V_c and V_t can be conveniently obtained from the values in the table for the calculation of the excitation, section 19. Then

$V_t = p \times$ (area path) $\times$ (length of path),
$V_c = 2\,p \times$ (area path) $\times$ (length of path).

The calculation of the core-loss is one of the most unreliable and unsatisfactory steps in the design, as the value calculated by theoretical principles has to be multiplied by a factor having a value between 1.5 and 3 to obtain the value of the core-loss that will be found in the finished machine, on account of the pulsations of flux caused by the teeth. This factor is obtained in commercial practice from tests on machines similar to the one being designed.

25. **Friction and Windage** can be calculated by formula for any particular line of similar machines but no method applicable in general can be given.

Machines are designed so that the value of the friction loss very closely approximates those given in the table in section 28. The true friction varies directly as the speed, and the windage as the square of the speed. In shunt machines the speed does not change much with the load so this loss may be assumed constant in this class of machines (*for series motors see article on that subject*).

Stray Power Loss. — This term is sometimes used to include both the core-loss and friction and windage.

26. Excitation Loss or RI^2 in Shunt Field. — Since in a self-excited machine the loss in the field rheostat is charged against the machine the total loss is equal to the terminal voltage multiplied by the current in the shunt field. The loss is usually constant and only subject to the arbitrary variations due to hand regulation.

27. RI^2 Loss in Armature Circuit, including the brushes, series field and connections, varies as the square of the armature current, and, therefore, approximately as the square of the load, and also irregularly to a small extent due to the variation of brush contact resistance with the value of the current. The temperature of the copper must also be considered. (*See Resistance and Conductance.*)

28. Efficiency. — The efficiency is the ratio of the output to the sum of the output and all losses. It is predetermined by estimating the value of each loss for the particular condition of load under consideration, as described in the preceding paragraphs.

If P = the output in watts and the symbols A, B, C and D represent respectively the values in *watts* of the various losses described in sections 24, 25, 26 and 27 for the load P, then

$$\text{Per cent efficiency} = \frac{10^2 \times P}{P + A + B + C + D}.$$

The efficiency is a maximum for that load at which the variable loss D is equal to the sum of the constant losses $A + B + C$. Hence the desirability of making the constant losses small in a machine which is to be operated most of the time at a small load.

Usual Efficiencies and Losses. — An idea of a reasonable value for the efficiency of d-c. machines of various sizes and the distribution of the losses is given in the following table. It must be remembered that the efficiency of a machine of any given size may vary throughout a wide range depending upon the speed, weight and cost.

Rating, kw.	Efficiency, per cent	Friction (total), per cent	Excitation, per cent	Core-loss, per cent	Arm. RI^2, per cent
1	80	6	6	4	4
5	84	5	4.2	3.2	3.6
10	86	4	3.6	3.0	3.4
20	88	3	3.0	2.8	3.2
50	90	2.6	2.2	2.2	3.0
100	91.4	2.3	2.0	1.7	2.6
200	92	2.2	1.8	1.6	2.4
500	93	2	1.6	1.4	2.0

29. **Regulation** is not very important in a d-c. generator as compounding provides a means of obtaining any desired voltage at full load. Most generators are designed with a series field which will give 15 per cent overcompounding at full load. If less compounding effect is desired a certain portion of the load current is shunted by the series field, which adjustment is made by trial.

The inherent regulation of a shunt generator may be predetermined as follows: Let C (*see section 19*) be the total excitation in ampere-turns per pole to give a voltage E at the terminals at full load. C is made up of the m.m.f. to produce flux for $E + RI$ and the m.m.f. to overcome armature reaction. Let E_0 be the voltage at no load for an excitation C as shown by the no-load saturation curve. Then

$$\text{Per cent regulation} = 100\,\frac{E_0 - E}{E}.$$

30. **Heating.**—The rise in temperature of the field coils was found in section 22. The rise in temperature of the armature conductors was roughly checked in section 14, but it is necessary to determine more accurately the probable rise in temperature of the armature conductors as the heat due to the core-loss affects the rise in temperature of the armature windings. The following method given by Arnold takes into account all the variables in this complex problem and with a correct choice of constants gives very reliable results. The dimensions are as indicated in Fig. 18.

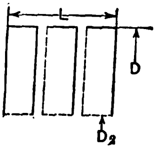

Fig. 18. Radiating Surface of Core

The surface of the armature core itself is taken as the sum of the outer cylindrical surface, the two annular surfaces at the ends, and one-half of the annular surfaces in the air ducts. Only one-half the surface in the ducts is used since this surface is not as effective as the external surfaces. It is assumed that the energy dissipated by this surface consists of the core-loss and that portion of the armature R_aI^2 which occurs in the portion of the conductors embedded in the slots.

A part of the heat due to R_aI^2 in the conductors flows from the copper through the slot insulation to the iron, if the temperature of the copper is higher than that of the iron. Sometimes, however, at light loads for instance, the temperature of the iron is greater than that of the copper and the flow of heat is reversed. This condition is taken care of in the following method.

The remainder of the heat due to R_aI^2 is dissipated through the insulation on the end connections to the surrounding air which is in motion due to the peripheral speed of the armature.

Power in watts dissipated by surface of armature core is

$$P_1 = \text{core-loss} + R_aI^2\left(\frac{2\,L}{l}\right),$$

I = full-load current; R_a = resistance of armature winding; L = total length of core; l = mean length of armature turns.

Effective radiating surface of armature core in square inches is

$$A_i = \pi DL + \frac{\pi}{4}(D^2 - D_2^2)(2 + d).$$

D = outside diameter of armature (Fig. 15); D_2 = inside diameter of armature; d = number of air ducts.

Rise in temperature in ° C. of armature core above air is

$$T_i = \frac{P_1}{A_i}\,t.$$

$t = 30$ for narrow, or high-speed armature; $= 40$ for long or slow-speed armature.

Permeance of heat path from copper to iron through slot is

$$M = \frac{U_s L s}{k_1 d_1},$$

where

U_s = perimeter of slot insulation; s = total number of slots; $k_1 = 200$ to 250; d_1 = thickness of insulation in slot; L = length of core.

Heat power in watts transferred from copper to iron or vice versa is

$$Q_1 = M\ (T_c - T_i),$$

where

T_c = rise in temperature of copper above air

Permeance of heat path from copper to air at end connections is

$$N = \frac{U_c l_c Z}{k_2 d_2 + k_3},$$

where

U_c = perimeter of end connection; l_c = length of end connection; Z = total number of bars or coil sides; $k_2 = 400$ to 500; d_2 = thickness of insulation on end connection; $k_3 = \dfrac{170}{1 + 0.00025\ V}$; V = periphery speed of armature, feet per minute.

Heat power in watts transferred from copper to air by end connections is

$$Q_2 = NT_c.$$

Total power of $R_a I^2$ in armature winding is

$$P_2 = Q_1 + Q_2 = M\ (T_c - T_i) + NT_c.$$

Whence, by transposal, the temperature rise, in °C., of copper of conductor above surrounding air is

$$T_c = \frac{P_2 + MT_i}{M + N}.$$

Explanation of Constants and Choice of Values:

t is the rise in temperature per watt per square inch at the surface of the armature or the specific drop in thermal potential from iron to air. It is affected by the peripheral speed and by the length of the armature.

k_1 is the drop in thermal potential per watt per square inch for slot insulation having a thickness of one inch. For any other thickness d_1, the drop is $k_1 d_1$.

k_2 is the drop in thermal potential per watt per square inch for insulation on end connections when the thickness is one inch, $k_2 d_2$ for any thickness d_2.

k_3 is the drop in thermal potential per watt per square inch between the surface of the insulation and the surrounding air. For stationary conditions $k_3 = 170$. As the peripheral velocity increases k_3 decreases.

Usually four-coil sides are bound together in the slot but separate on leaving the slot. Hence the reason for using s and Z in the different equations.

TESTING OF DIRECT-CURRENT MACHINES. — Direct-current machines are judged by four characteristics: efficiency, regulation, commutation and heating. It is necessary to subject a machine to actual full-load conditions to determine its heating and commutation and it is desirable to do so to determine the regulation, but the efficiency is determined more accurately by the "separate loss method" which does not involve loading the machine.

The customary tests on d-c. machines are: (*see also Standardization Rules.*)

(1). Resistance measurements, cold and hot. (2). Saturation curve. (3). Core-loss and friction test. (4.) Load run for commutation and regulation. (5). Heat runs. (6). Compounding test. (7). Insulation test.

1. **Resistance Measurements** — The first measurements are made when the machine is at the same temperature as the room, that is, after it has been idle from 12 to 24 hours depending upon its size. This is in order that the relation between the resistance and temperature may be accurately known. The resistance of the shunt-field, series-field and armature winding proper are measured.

Resistance of Lap Winding. — In measuring the resistance of the armature winding it is preferable to measure between two diametrically opposite points of the commutator of a multiple-wound armature. The effective resistance of the armature is calculated from this by the formula

$$R_a = \frac{4 R'}{p^2},$$

where R' = resistance measured as above, and p = number of poles.

Resistance of Wave Winding. — In measuring two-circuit series-drum windings it is necessary to measure between two commutator segments separated by a distance equal to the periphery of the commutator divided by the number of poles. This will give the effective resistance of the armature.

Brush Contact Resistance. — The resistance of the brushes and brush contact is calculated from data such as given in section 15 in the above section on *Design;* a measurement made with the actual circuit is not very satisfactory. However, it is sometimes the practice to measure the resistance of the entire armature circuit from brush to brush by the drop in potential method for several values of current, the armature being at rest. This is not accurate, however, as the resistance of brush contacts depends upon the speed.

2. **Saturation Curve.** — The saturation curve is not of immediate interest in determining the quality of a machine but is more particularly of interest to the designing engineer. It is made by driving the armature at the proper speed and supplying current to the shunt fields from a separate source of potential. As the current in the shunt field increases the potential generated by the armature varies and this is measured by a voltmeter.

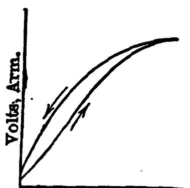

Fig. 19. Saturation Curve

On account of the existence of the hysteresis loop (*see Magnetic Properties of Iron*) it is necessary to increase the field current gradually and never to reduce the value at any step until the maximum value has been reached. The curve is plotted with volts as ordinates, and field current or ampere turns as abscissæ and shows the typical knee curve of all saturation curves. Different curves are obtained with increasing and decreasing excitation as shown in Fig. 19.

3. **Core-Loss and Friction, or Stray Power.** — These tests are made with the same arrangement as used in determining the saturation curve, and may be made at the same time. The machine to be tested is driven by a small motor having a capacity about 10 per cent of the rating of the machine under test. All the losses and constants of this motor must be known.

First the machine under test is driven at the desired speed with no current in the fields and the power taken by the driving motor noted. The mechanical output of the driving motor is calculated and this gives the friction loss of the large machine.

Then the large machine is excited and the power to drive it is determined. This power represents the core-loss plus the friction loss. Deducting the friction loss already determined, the values of the core-loss for various values of excitation are found. See also *Magnetic Properties of Iron*.

The combined core-loss and friction loss constitute the stray power loss.

4. **Load Runs.** — The machine is run and the excitation adjusted to give the proper voltage at no load. The load is then added and the terminal voltage noted. If E_0 = voltage at no load and E = voltage at full load, the regulation is $\frac{E_0 - E}{E}$.

If the machine has not commutating poles it is necessary to make a preliminary test in order to set the brushes at that position which gives the best compromise in sparking at no load and full load. Commutation is judged by observing the action of the brushes at full load and 150 per cent load. The conclusions are a matter of judgment and experience, although degrees of sparking have been arbitrarily agreed upon and are represented in a chart or series of pictures.

5. **Heat Runs** are made by operating the machine at full load for a period of time until the temperatures of the various parts that can be noted during operation have become constant. The greater the capacity of the machine the longer will be the time necessary.

Dead-load and Pumping-back Methods. — Heat runs may be made either by the "Dead Load" method in which a resistance load, such as a water-rheostat, is connected to the terminals and full rated load power is required to drive the machine; or by the Hopkinson or "Pumping-back" method in which two machines having similar characteristics are run together, one acting as a generator to supply electrical power to the motor which in turn drives the first by means of a belt or similar mechanical connection. For this test a "loss-supply" is required which may consist of a source of either electrical power or mechanical power. The amount of power required is from 10 to 20 per cent of the rating of one of the machines. The connections are shown in Fig. 20, for electrical loss supply and Fig. 21 for mechanical loss supply.

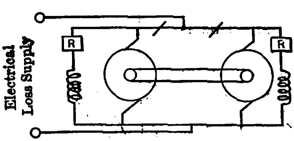

Fig. 20. Hopkinson Load Test, Electrical Supply of Losses

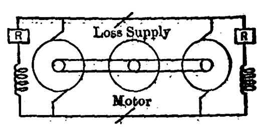

Fig. 21. Hopkinson Load Test, Mechanical Supply of Losses

Thermometer Readings. — During the heat run there are taken at stated periods, readings of thermometers which show the temperature of the frame, field coils, bearings and surrounding air. After the heat run the thermometers are placed on various parts of the machine, the bulbs being protected from radiation by small pads of cotton, and the following temperatures are noted:

Armature-core surface;	Field coils;
Armature-core ventilating ducts;	Bearings;
Armature conductors or winding;	Frame;
Commutator surface;	Room.
Pole tips;	

The resistance of all electrical circuits should be measured and the average temperature of the copper calculated from the formula,

$$t_1 = \frac{R_1}{R_0}(239 + t_0) - 239,$$

where R_1 and R_0 are the hot and cold resistances respectively, and t_1 and t_0 the hot and cold temperatures respectively, 98 per cent conductivity copper being assumed. See article on *Copper.*

6. **Compounding Test.** — In order to adjust the current in the series field so that a compound-wound generator will give specified voltages at no load and full load, the machine is first operated at no load and the current in the shunt field is adjusted to give the desired no-load voltage. The load is then put on and usually it will be found that at full load the terminal voltage is too great. Strips of German silver or other resistance metal are then connected in multiple with the series field until by shunting current from the series field the voltage is reduced to such value as is desired. This shunt resistance is then made up in permanent form and connected in circuit. Before making the no-load adjustment it is desirable to overexcite the shunt field for a moment in order to over come the hysteresis. See also section on *Parallel Operation* below.

7. **Insulation Tests.** — After the heat runs it is customary to apply a high-potential test to the insulation of the machine. This consists of applying an alternating potential between each electrical circuit and the frame of the machine for one minute. The value of the potential depends upon the capacity and rated voltage of the machine under test and is definitely specified in the Standardization Rules of the A. I. E. E. (*q. v.*).

EXAMPLES OF DESIGN AND PERFORMANCE. — In the tables on pp. 680 and 681 will be found the essential data including mechanical, electrical and magnetic characteristics of four examples of direct-current machines. In these data are included all the factors necessary to determine the efficiency, regulation, commutation and heating of the machines. Dimensions are in inches and weights in pounds. Performance data are deduced from tests.

SERIES ARC-LIGHT GENERATORS. — These machines are intended to give a constant value of current in the external circuit irrespective of the resistance or counter e.m.f. in that circuit. This is accomplished by causing the voltage impressed on the external circuit to decrease whenever there is a tendency of the current to increase. The load usually consists of a number (20 to 50) of arc lamps connected in series, each taking about 40 volts. Each lamp requires the same value of current and the total voltage is proportional to the number of lamps in use. If a lamp is no longer needed it is short-circuited by a switch and the current in the remainder of the lamps remains the same because the generator automatically reduces the voltage supplied. This regulation of the current is obtained by two or more of the following methods: (1) high armature reaction which tends to weaken the field whenever the current increases; (2) movable brushes to vary the number of turns in series between brushes; (3) a series field arranged so that turns may be shunted, short-circuited or cut out; and (4) a high degree of saturation in the magnetic circuit of the field so that the flux changes very slightly for considerable change of m.m.f.

The pole face density is usually quite high and the path of the flux in the field is of high reluctance, whereas the path of the armature flux is of low reluctance; thus there is much field distortion. The machines are usually wound for 2000 to 4000 volts. The distorting effect of armature reaction is usually relied upon to take care of sudden and small variations of the load, and large and lasting variations of the load are taken care of either by moving the brushes to another

position giving either a lower or higher voltage, or by commutating or shunting some of the turns of the series field.

Brush Arc Machine. — This was the first arc-light machine to be brought out. It consists of a ring armature having a winding of the open-circuit type. There are a number of spool-wound coils on the armature, diametrically opposite coils being connected in series to an independent pair of commutator segments. The brushes make a series connection of the various groups of coils, the coils of highest e.m.f. being connected in series, those of medium e.m.f. in multiple and those of low e.m.f. being left out of circuit. The numerous field poles are on both sides of the ring armature. The two poles facing each other are of the same polarity so that the flux flows along the ring of the armature from one pole to the next pole on the same side of the ring. Regulation is obtained by shunting field turns and shifting the brushes for good commutation. A rotary oil pump is used as a regulator to move the handle of the field regulator and to move the brushes.

Thomson-Houston Arc Dynamo. — This machine contains a spherical-shaped armature with a three-part open-circuit winding. The three windings being spaced at 120° on a ring armature and connected in "Y," the terminals going to the segments of a three-part commutator. The commutator has air spaces between segments and a jet of air to blow out any arcs between brushes and segments. There are four brushes on the commutator, connected in pairs. At some part of each revolution two coils are in multiple, at other positions only one. A relay moves the brushes so that as the load increases the positive and negative brushes move farther apart thus giving more voltage. As one brush of a pair moves forward the other moves backward thus keeping them symmetrical with respect to the neutral axis. The field structure is of a hollow, cage-like construction.

Wood Arc-light Machine. — This generator has a closed-circuit Gramme ring armature with a commutator having a large number of segments. Regulation is obtained by moving the brushes so as to vary the voltage available and by the use of a high armature reaction balancing the field m.m.f.

HOMO-POLAR GENERATORS. — This type of machine is also sometimes called "acyclic" and was formerly incorrectly called uni-polar. Its method of operation is based on the principle of the Faraday disk, which consisted of a copper disk revolving about an axis and projecting between the poles of a magnet. By this rotation in a magnetic field an e.m.f. is set up between the axis and the periphery of the disk, and if brushes bearing on these two parts are connected to an external circuit a current will flow. The peculiar characteristic of a homo polar machine is that each conductor always cuts the flux in the same direction, consequently the e.m.f. induced in it is always in the same direction and is not alternating as in the usual direct-current machine. Thus no commutator is required.

This absence of a commutator is the feature which makes the homo-polar machine attractive. The commutator presents many difficulties in high-speed machines to be driven by steam turbines. It is for this application that recent attempts to develop a successful homo-polar machine have been directed. Instead of a commutator, collector rings with brushes are used to collect the current from the moving conductors. These collector rings, however, present difficulties in construction and operation on account of the high peripheral speed at which they must run. The rings are subject to a considerable centrifugal force and there is a tendency of the current to arc between the brush and the collector on account of the high rubbing speed.

Voltage. — The voltage of such a machine is not only unidirectional as in all direct-current machines but is really constant. But since there can be only a

few conductors in series, the voltage generated is very low. The voltage generated per disk or inductor is

$$E = Blv\,10^{-8},$$

where B = magnetic lines per sq. cm., l = length of conductor in cm., v = velocity of conductor in cm. per sec.,
This is more conveniently expressed,

$$E = \frac{NZ\phi 10^{-8}}{60} \text{ volts},$$

where N = revolutions per minute, Z = conductors in series, ϕ = total flux traversing gap.

Radial and Axial Types. — There are two types of homo-polar machines, the radial and the axial. The radial type (Fig. 22) is like the Faraday disc and consists of a disc revolving between the two poles of a cylindrical magnet. Brushes bear on the outer rim and the shaft to collect the current. The disc may be made of steel to reduce the reluctance of the magnetic path. The voltage of such a machine is limited to 10 or 15 volts but the current may be

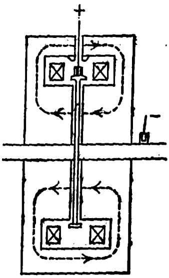

Fig. 22. Radial Type of Homo-polar Generator

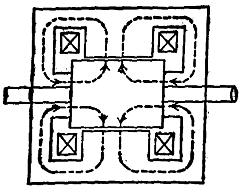

Fig. 23. Axial Type of Homo-polar Generator

very large. A variation of this type has two discs on the same shaft and the magnetic path so arranged that the voltage of the two discs may be added in series by brushes bearing on the peripheries of the two discs. The axial type (Fig. 23) consists of a cylindrical steel armature with copper bars in the surface, the whole revolving in a cylindrical field so arranged that the magnetic flux flows outward from the armature in a radial direction at all points. The several conductors on the armature are connected to slip-rings at both ends, and by means of brushes and stationary conductors, these conductors are connected in series. The voltage of such a machine may be from 40 to 50 volts per conductor.

Data on Large Axial Type Machine. — In the *Trans. A.I.E.E., Vol. 24,* Noeggerath describes a machine of the axial type rated at 300 kw. for 500 volts at 3000 r.p.m. The armature has 12 conductors connected in series for 500 volts. The diameter of the armature is 19 inches and the length 12 inches. The peripheral velocity is 15,000 ft. per min. The armature is of cast steel and has 24 cast steel collector-rings on it. The stationary conductors connecting the collector-rings together are placed in the face of the pole and thus their m.m.f. may be used to balance the armature reaction.

Excitation. — The armature reaction of such machines is very high and has only a distorting effect. However, it weakens the field as the cross magnetiza-

tion weakens one part more than it strengthens another due to saturation. By a proper arrangement of the movable connections between the collector-rings and stationary conductors a m.m.f. may be set up which will strengthen the field and thus the machine may be compounded. These machines may be made self-exciting but the resistance of the shunt fields must be very low in order that the machine may pick up on starting as the resistance in the brush contacts is high. The drop in voltage in each brush contact is about 0.8 volt at full load but is higher before the current flows. It sometimes requires from 10 to 20 times the normal voltage of brush contact to start the current.

Losses. — Such a machine as described above has an efficiency of approximately 90 per cent at full load. The losses are made up principally of friction and I^2R in the brushes. The field I^2R is low as the air gap is small for mechanical considerations. The armature I^2R is almost negligible due to the few turns. The eddy losses are low if the flux density is constant in one zone around the armature but the density may vary along an element of the cylinder. The total weight of the machine is about the same as for the usual d-c. machine but the proportion of copper is much lower than in the usual machines.

SPECIFICATIONS FOR D-C. GENERATORS.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Principal Characteristics and Conditions of Service. — Service for which it is to be used, such as railway, lighting, etc. Voltage. Rated output, kilowatts. Speed.

Style and Description, Details of Construction. — Type, whether shunt or compound wound. Whether interpole. Details of speed and governing of prime mover and how generator is connected to prime mover, e.g., direct or belt driven by steam turbine, reciprocating engine, water wheel, water turbine, gas engine, oil engine, etc., with vertical or horizontal shaft. If field rheostat is to be supplied, its characteristics, including the effect upon the generator voltage of each step and of all steps; accessibility of armature. If belt driven, specify pulley details.

Work to be Done by Other Contractors. — *See Generators, Alternating-Current*, under same heading.

Performance and Tests. — (*See Standardization Rules of the A.I.E.E.*). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 1/4, 1/2, 3/4, 1, and 1 1/4 loads. (Whether rheostat losses to be included in calculating efficiencies.) High potential tests of insulation. Requirements regarding effect of moisture upon insulation. When run at constant rated speed, the load may be varied from zero to a stated per cent of rated load without causing more than a stated variation of voltage, the field rheostat being kept constant.

INSTALLATION. — In installing a d-c. machine the following precautions must be observed:

1. For large machines with foundations the foundation bolts must be provided in accordance with drawings.

2. Bearings must be lined up and well cleaned before being filled with oil.

3. The armature must be properly centered so that the air gap is correct at all points. Taper wedges are used to measure the gap. The magnet frame should be bolted to the base.

4. The field coils must be properly connected. Test for polarity with a compass in order to make sure that no field coils are reversed. For a self-

* By W. A. Del Mar.

exciting generator there is one particular connection of the field to the armature for each direction of rotation.

5. The commutator must be smooth and polished; use sandpaper to polish the commutator, never use emery cloth.

6. The brushes must be properly and accurately spaced around the commutator. They must be sandpapered and fitted to the curvature of the commutator. The pressure on the brushes must be adjusted to the correct value which is usually 1.5 to 2 pounds per square inch of contact surface.

7. The machine must be thoroughly dried out by heating and the insulation measured as a check.

OPERATION. — In starting up a single generator it is sometimes necessary to "charge" the field by separately exciting the shunt fields for a moment to set up residual magnetism.

To cause the machine to "pick up" or generate voltage by self-excitation it is necessary to cut out or short-circuit most of the resistance of the regulating rheostat connected in series with the shunt field. If the total resistance of the shunt-field circuit exceeds a certain critical value the machine will not "pick up," however much time is allowed.

Parallel Operation. — In order to operate a power station under economical conditions it is necessary to have a number of machines whose aggregate capacity is equal to the maximum demand on the station. As the demand varies the number of machines in operation is adjusted so that the machines running are operating at a load near their rating, and, therefore, at a good efficiency.

Shunt Generators. — In order to operate shunt generators in parallel, that is, feeding the same bus-bars, it is only necessary to adjust them all to the same polarity and voltage, connect them to the bus-bars, and adjust the division of load by strengthening the field of the underloaded machine if the voltage of the bus-bars is low. If the voltage of the bus-bars is high, weaken the field of the overloaded machine.

Compound Generators, Equalizer Connection. — In order to operate compound-wound machines in parallel it is necessary to provide an equalizer connection which makes a common connection on all the machines at the point between the armature and the series field as shown in Fig. 24.

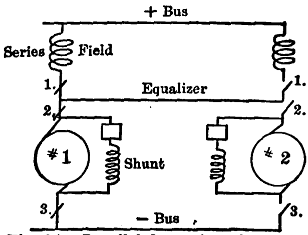

Fig. 24. Parallel Operation of Compound-wound Generators

The function of the equalizer is to divide the load current at all times in the proper proportion between the series fields of the different generators. This prevents the machines from acting as series generators or differential motors which would cause short-circuits.

For compound-wound machines to operate successfully in multiple all machines connected to one set of bus-bars must have the same amount of compounding as well as the same voltage at no load. Due to saturation in the magnetic circuit it is not always possible to make the compounding curve a straight line, i.e., the increase in voltage directly proportional to the load. It is, therefore, necessary to investigate the compounding curves of machines before they are operated in parallel. With unlike compounding curves one machine may become overloaded while another is under-loaded, unless the field current of one machine is adjusted.

In connecting a machine in parallel with those in operation it is necessary to see that it has the proper polarity and voltage, that the equalizer circuit is made,

and that the switches are closed in the order 1, 2, 3 as shown in Fig. 24. If any other order is used the effect is the same as having no equalizer.

In shutting down one machine switch No. 3 must be opened first, and then No. 2 and No. 1.

COST, WEIGHT AND SPEED. — In Figs. 25, 26 and 27 will be found the weight and cost per kilowatt of direct-current generators for usual or standard speeds. Fig. 25 gives the weight and cost of a line of high-speed machines for the suitable speeds shown by the curve. Fig. 26 gives the same information for a line of moderate-speed machines, generators or motors, and Fig. 27 for a line of slow-speed generators designed for direct connection to steam engines.

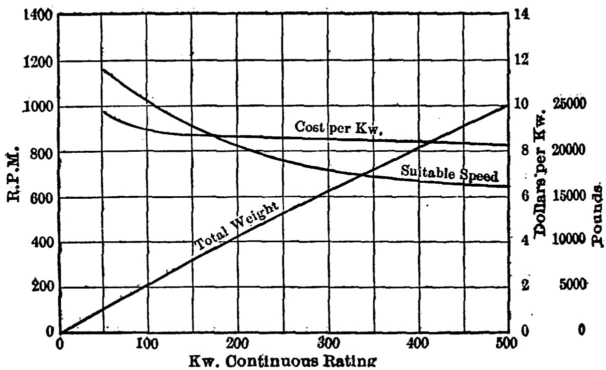

Fig. 25. Data on High-speed D-C. Machines

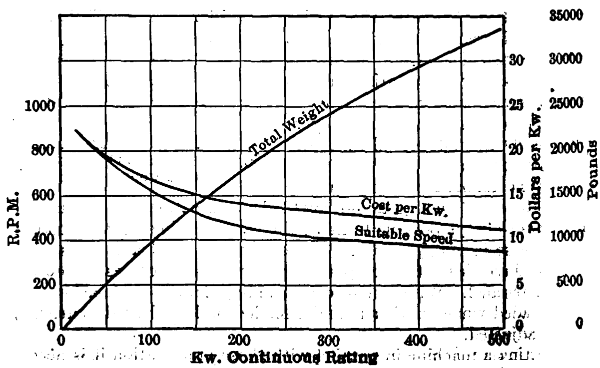

Fig. 26. Data on Moderate-speed D-C. Machines

GENERATORS, STATIC. — (*See also Generators, Alternating-current; X-Rays.*) In electro-therapeutic and X-ray work a unidirectional high-frequency current is desired and is often obtained by a kind of electric generator called a static generator. There are two types of static generators available for the purpose, the frictional machine and the influence machine.

Frictional Machine. — In the frictional machine two dissimilar substances are rubbed together in some form of rotating apparatus as shown in Fig. 1. A rotating glass plate *A* is rubbed on both sides at *BB* by two pieces of leather which are greased and covered with the amalgam 1 Zn, 1 Sn, 2 Hg. The glass is electrified positively and the charge is drawn off by the metal points *CC* which almost touch the glass. Two silk aprons *DD* cover the glass between the rubbers and the metal points, to prevent the leakage of the charge into the air. The rubbers are connected to ground to remove the negative charge which accumulates upon them.

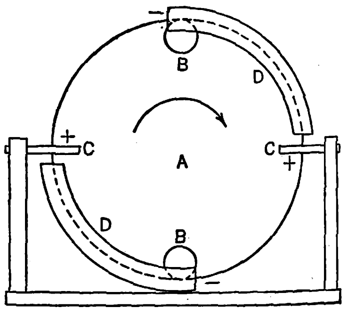

Fig. 1. Frictional Machine

Influence Machine. — The influence machine generates an e.m.f. by electrostatic induction, the principle of the action being clearly shown (see Fig. 2) in a machine invented by G. Belli in 1831. Two spheres or disks *AA*. called carriers and normally insulated from each other, are rotated about the shaft *B*. The two fixed plates *CC* are charged initially from some external source. When the carriers *AA* take the position shown in the figure, a momentary connection is made to the neutralizing wire *E* at the spring contacts *DD*. As a result of this connection between *A* and *A*, the carriers are charged by induction, the charge on each being opposite to that of the adjacent plate. When the carriers rotate still further, the connections at *DD* are broken and the charges induced on the carriers become isolated. When the carriers are rotated through half a revolution from the position shown, they strike the springs *FF* and add their charges to the field plates *CC*.

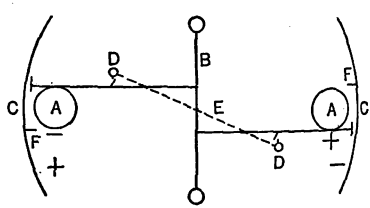

Fig. 2. Influence Machine

Wimshurst Machine. — Many forms of influence machines based upon the above principles have been devised. The most successful designs were made by Toepler, Holtz and Wimshurst. The Wimshurst machine, shown in Fig. 3, has superseded most of the other forms because of its self-exciting powers and suitability for work in all conditions of atmosphere. Two glass disks, *A* and *B*, are rotated close together and in opposite directions. A certain number of tin-foil carriers *CCC*, are mounted upon the outside surface of each plate. Neutralizing conductors *DD* for each disk are placed at right angles to each other. The collecting combs *EE* are connected to a condenser *F* and a spark gap *G* across which the discharge takes place. If two diametrically opposite

carriers on the back plate are charged positively and negatively respectively, opposite charges will be induced upon the adjacent carriers on the front plate if they are connected by the neutralizing wire. The induced charges are isolated when this connection is broken and are drawn off at the collecting combs *EE*. In the Wimshurst machine induced charges in moving from the point of electrification to the collecting combs also serve to induce other charges on the back plate.

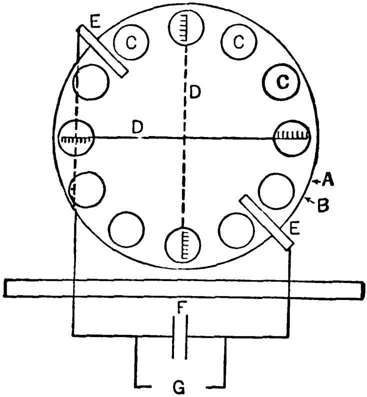

Fig. 3. Wimshurst Machine

After a few revolutions of the disks, half of the carriers on each plate are charged negatively and half positively, giving a machine of reliable service and high power. Unlike the Holtz machine the Wimshurst machine does not reverse its polarity when the distance between the terminals is made greater than the sparking distance. Large influence machines are constructed with several plates revolving in opposite directions and connected in parallel, the whole being contained in a glass case to protect the plates from dust. An eight-plate Wimshurst machine gives a spark of eight inches and a twelve-plate machine will give a spark of 13⅝ inches. The plates in these machines are approximately 30 inches in diameter and the machines give 6 sparks for each revolution of the disks.

GROUND CONNECTIONS. — (*See also Grounding of Electric Circuits.*) A ground connection is a conductor buried in the earth and connected by conductors to other conductors or apparatus which are to be maintained at earth potential, irrespective of the current which may flow through it. Usually a circuit is not grounded except at such points that under normal conditions of operation no appreciable current flows to ground. A current may, however, be established through a ground connection due (1) to a lightning discharge, (2) to an accidental grounding of a live wire of a grounded circuit, and (3) to a cross between the grounded circuit and a high voltage ungrounded circuit; in the last instance the current through the ground connection is only the relatively small charging current between the other wires of the high voltage system and the ground (*see Capacity and Charging Current*).

USE OF GROUND CONNECTIONS. — Ground connections are used for the following purposes: (1) for lightning arresters, to afford a path to ground for the lightning; (2) for lightning rods on buildings, for the same purpose; (3) for steel transmission poles to give the current a short circuit to ground in case of insulator failure. Also as a lightning protection; (4) to bring the neutral points of circuits to ground potential and thus reduce the potential stresses of the system and minimize the danger of accident from shock; (5) to bring transformer cases, instrument cases, conduits, etc. to ground potential and thereby reduce the danger from shock; (6) to obtain an earth return for telegraph circuits; (7) for wireless telegraph systems to obtain the use of the earth's electrostatic capacity.

GROUNDING TO CONDUCTORS USED FOR OTHER PURPOSES. — Where an extensive system of water pipes buried in the earth is available, a satisfactory ground connection can be made directly to the pipes. Gas pipes are not suitable for ground connections, as in case of broken joints the resulting arc might ignite the escaping gas. Steam heat pipes are heat insulated (and therefore partially electrically insulated) from the earth. Where there are two ground connections, one to an electric railway track and the other to a water pipe, there is danger that railway current may thereby be introduced into the water piping system and produce electrolysis. Sheaths of cables are not good ground as the cables might be injured by the currents in their sheaths, either from electrolysis or unforseen heating. In fact, cable sheaths, like other buried conductors, have a tendency to collect stray currents from electric railways and special ground connections sometimes have to be made to permit these currents to escape without producing electrolysis. Steel frames of buildings present only a limited surface to ground at the foundations and are therefore only good when the current to be discharged will be proportionally small.

Connections to Piping System. — The National Electrical Code contains the following requirements:

Size of Ground Wires. — Not to be smaller than No. 6 B. & S. copper for lightning arresters (rule 5-c), or for grounding low potential circuits (rule 15-d), also not to be smaller than neutral for grounding three wire direct-current systems (rule 15-d), or less in carrying capacity than any one of the three mains for grounding three-phase systems (rule 15-d).

Method of Making Ground Connection. — In connecting a ground wire to a piping system, the wire should be sweated into a lug attached to an approved clamp, and the clamp firmly bolted to the water pipe after all rust and scale have been removed; or be soldered into a brass plug and the plug forcibly screwed into a pipe fitting, or where the pipes are cast iron, into a hole tapped into the pipe itself. For large stations, when connecting to underground pipes,

with bell and spigot joints, it is well to connect to several lengths, as the pipe joints may be of rather high resistance.

GROUNDING TO SPECIAL PLATES, PIPES, ETC. — When suitable buried conductors are not already available, direct connection to the ground may be made (1) by burying a plate in the earth, (2) by burying a wire or ribbon in the earth, or (3) by driving a pipe vertically into the earth. The last form of ground connection is now (1914) generally accepted as the best. These three methods of direct grounding are described in detail in the section below on *Design*.

Factors Affecting the Resistance of Ground Connections. — The resistance opposing the flow of current into the ground through a ground connection depends (1) upon the extent of metal surface in contact with the earth, (2) the thoroughness of this contact, (3) the wetness of the earth, (4) the distance between this ground connection and the ground connections (if any*) at which the current leaves the earth.

The effect of the distance upon the resistance between the electrodes is an important one, but is frequently overlooked. If the electrodes are close together, the resistance will be low on account of the shortness of the current path. If the distance between electrodes be increased, the resistance will be increased until a certain point is reached, after which it will steadily decrease on account of the increase in the cross-sectional area of the earth path. In the experiments the Cunliffes (*Jour. I.E.E., 1909, Vol. 43, p. 449*) the resistance reached a maximum when the ground plates were about 25 feet apart, the decrease in resistance being quite sudden for smaller or greater distances, as shown in Fig. 1. A curve by E. E. F. Creighton (*G. E. Rev., 1912, Vol. 15, p. 69*) shows the resistance between pipe grounds at various distances apart, the maximum resistance being again attained at 25 feet.

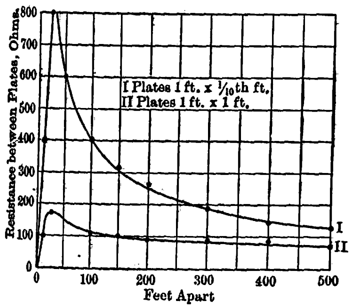

Fig. 1

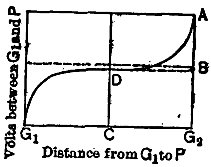

Fig. 2.

Definition of the Measure of the Resistance of a Single Ground Connection. — If the distance between ground connections be fixed and the drop of potential from one of them G_1 and a point P between them be plotted against the distance of P from G_1 a curve such as G_1DA, Fig. 2, will be obtained, if the two ground connections G_1 and G_2 are similar. If, on the other hand, the ground connection G_2 has very much more perfect and extensive contact with the earth, the curve of potential drop will have the shape G_1DB. Both curves have the peculiarity of being steep near the electrodes and of becoming flat between them, indicating that the greater part of the resistance occurs near the electrodes,

* The circuit may be completed by a displacement current through the air from the surface of the earth.

where the current is restricted to a limited area, practically no drop occurring where the current spreads out.

The resistance of the ground connection G_1 is then defined as the ratio of the potential drop CD, to the current entering the ground at G_1, and similarly for the ground connection G_2.

Resistance of Some Typical Ground Connections. — The resistance of ground connections varies so greatly with the condition and nature of the soil, that data on resistance have only local application. The following tests are presented merely to give a general idea of the results which are obtained in practice.

Authority	Time of year	Description of soil	Type of ground connection	Dimensions	Depth	Ohms
					ft.	
Hoxie.....	Feb.–June	Surface loam	Plate	1 ft.×1 ft.	..	1940
	Feb.–June	Moist black loam	Plate	6 ft.×2 ft. 3 in.	6	113

Hayden...	June–July	Clay loam	Pipe	2½ in.	3.1	35.4
	Mch.–Apr.	Clay loam	Pipe	2½ in.	3.1	240

E. E. F. Creighton (*G. E. Review, 1912, Vol. 15, p. 67*) says: "If an iron pipe one inch in diameter is driven into normally moist earth to a depth of 6 or 8 feet, it will usually have a resistance of about 15 ohms. Eight ohms may be considered unusually low, while dry soils may give a resistance of 56 ohms and upwards." Creighton also states that after a depth of several feet in the conducting stratum has been reached, each additional foot decreases the total resistance by the factor $1/d$ where d is the depth in feet.

DESIGN OF GROUND CONNECTIONS. — It is as a rule impracticable to install a ground connection of sufficiently low conductivity to allow the passage of the maximum current it may have to carry without producing a considerable rise of voltage. The conductivity which a ground connection should have is therefore largely a matter of experience and judgment rather than a matter of exact calculation. Cheapness and durability usually determine the material, usually iron or copper, and the thickness.

Copper Plates. — Until recently the most common form of ground connection consisted of a copper plate embedded in charcoal or coke in moist earth. The use of coke is questionable, for the reason that the sulphur in the coke is likely to corrode the copper plate and thus increase its resistance. Some engineers are of the opinion that neither charcoal nor coke is of any particular use in connection with a ground plate. The corrosion of copper ground plates is greatly reduced by coating with tin. As the conductance of a ground connection is not proportional to the area of the metal plate, the use of a single large plate is an uneconomical method of obtaining a low resistance.

Copper Wire or Ribbon. — The wire or ribbon has the advantage of a lower resistance than the plate for the same area. The wire has the further advantage that no special material or connection is required. The wire may be laid out in a straight line or coiled with turns wide apart into a plane spiral. The latter form is sometimes made by wrapping a number of turns of wire around the butt of a pole before setting it.

Pipes Driven into the Ground. — The driven pipe or rod is probably the best of all forms of direct ground connections. The pipe is usually an iron one, often galvanized or sherardized, from ¾ inch to 2 inches in nominal size, driven 6 feet or more into the moistest ground available. The diameter of a pipe has little effect upon its earth resistance; thus a pipe 2 inches in diameter has a resistance only 6 to 12 per cent less than a pipe 1 inch in diameter (E. E. F. Creighton, *G. E. Rev., 1912, Vol. 15, p. 14*). To facilitate driving, the pipe is sometimes provided with a pointed casting at the lower end and cap at the upper end. The pipe has the advantage that it is cheap to install, as no hole is dug, and being driven vertically, it can tap any conducting stratum of the earth which is practically accessible. It is highly efficient as regards conductivity per square foot of surface exposed to the earth, and while the resistance of a single pipe will exceed that of a large plate, a higher and more permanent conductivity can be obtained from several pipes driven at some distance apart and connected in multiple, than from an equal expenditure in money on a single large ground plate. Ground pipes or plates in multiple should be not less than 6 feet, and preferably 10 feet, apart, in order to avoid superimposing two zones of high current density.

If the ground available is naturally dry the conductivity may be improved by cupping out the soil around the pipe at the surface and adding a few pounds of salt and water. A neater form of earth unit is shown in Fig. 3. A cylinder of metal or earthenware of any available diameter is set around the pipe at the surface of the ground and covered by a lid. This receptacle will hold the salt. Its advantages lie in the easy construction of the connection and protection of surrounding vegetation from the saline water.

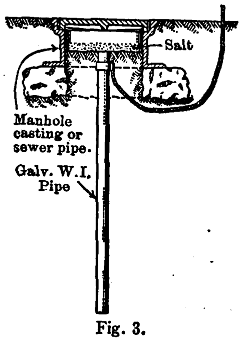

Fig. 3.

Pipe Grounds for Lightning Arresters. — The General Electric Company recommends a large number of grounds at each installation. These numerous ground connections are joined together by a copper connection. It sometimes happens that a good ground cannot be conveniently made near the arrester, or that a better one can be made at a more distant point. In this case it is recommended that the principal ground be made at the more distant point, but that a ground of some sort, the best possible under the conditions, be made directly underneath the arrester.

Connections to Ground Plates and Pipes. — The wire connecting the apparatus to be grounded to the buried conductor should lead directly to the latter with as few bends as possible; this is particularly important in grounding lightning arresters, in which case a flat strip is also better than a round wire. All exposed joints and those buried in the ground should be made in such a way that they will not rust off. The buried connection from a ground plate to the surface should be so protected that it will not rust off or be cut off when excavations are made for other purposes. It is also necessary that the connections be protected from mechanical injury and theft, from the surface of the ground

to above the level at which it can be reached. To insure reliability, connections should as far as possible be made so that their continuity can be determined by inspection.

Dimensions of Some Typical Ground Connections. —

TESTS OF GROUND CONNECTIONS. — Ground connections should be frequently tested to determine their continuity and occasionally to determine their resistance. Alternating current should be used, in order to avoid the effects of polarization. In order to pass a current through a ground connection it is necessary to have a second connection in order to complete the circuit. Where a large water piping system is available for the return connection, an approximate measure of the resistance can be obtained by passing a current from the ground connection to an accessible part of the piping, say a hydrant, and computing the resistance by dividing the volts by the amperes. The resistance thus obtained includes both the resistance to be measured and that of the connection through the piping system. As the latter is probably much the smaller and may be insignificant, the result gives an approximate idea of the resistance and locates a discontinuity as an infinite resistance, that is, no current flowing. Where there are two similar grounds, current may be passed from one to another and the sum of the two resistances, or the average resistance, obtained.

When a more accurate determination of the individual resistances of two or more ground connections is desired, the connections shown in Fig. 4 may be employed and a curve obtained by test, similar to that shown in Fig. 2. The apparatus required comprises a source of alternating current, a rod P which may be driven into the earth, a high resistance wire BD stretched between the two ground connections G_1 and G_2, an ammeter A and a telephone receiver T. The contact C is slid along the resistance wire until the telephone receiver is silent. The drop of potential between G_1 and the rod is then the same as between G_1 and the contact C. The drop between G_1 and P is therefore equal to

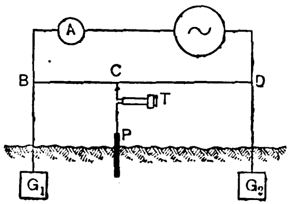

Fig. 4.

$$\frac{(\text{length of wire } BC)}{(\text{length of wire } BD)} \times (\text{total drop from } G_1 \text{ to } G_2).$$

By taking a series of observations with P driven into the ground at various points the curve of potential drop is readily plotted and the resistance of each ground connection, as defined above, readily obtained.

CARE OF GROUND PLATES AND PIPES. — The greatest trouble with ground plates and pipes arises from electrolysis, and periodic resistance measurements should be made as described above. When a ground connection shows an abnormally high resistance, it is usual to supplement it with a new ground connection, as it seldom pays to remove the old ones. Ground connections deteriorate rapidly if equipped with salt boxes; but even under the worst conditions they are likely to last many years. Practically no accurate measurements of the resistance of ground connections were made until quite recently, so that little is known about their life performance. J. L. R. Hayden cites the case of some pipe grounds which maintained the same average resistance for three years.

SPECIFICATIONS FOR GROUND PIPES AND PLATES. — (*See also article on Specifications.*) In the case of ground plates, the following data should be specified: Material of plate (usually copper); size of plate, area and thickness; depth at which the plate shall be buried; amount of charcoal below and above it; method of connecting the plate to its cable or wire (usually soldered and bolted); whether the plate shall also be connected to the track rails and if so, how.

In the case of pipe ground connections, the following data should be specified: Diameter of pipe; whether galvanized, sherardized, etc.; depth to which the pipe shall be driven; method of finishing the top of the pipe; height the pipe shall project above the ground; whether the pipe shall be connected to the track rails and if so, how.

[W. A. DEL MAR.]

GROUND DETECTORS AND ARCING-GROUND SUPPRESSORS. — A ground detector is a device for indicating an accidental ground on a transmission line; an arcing-ground suppressor is an arrangement of switches and relays by means of which an arc tending to maintain an accidental ground is automatically extinguished

GROUND DETECTORS FOR NORMALLY UNGROUNDED SYSTEMS. — On ungrounded two-wire direct-current systems a voltmeter of the central-zero type connected between the ground and the middle point of a resistance joining the two line wires serves as a satisfactory ground detector. The direction of the deflection will indicate on which wire the ground has taken place, and the magnitude will indicate the nature of the ground. For alternating-current circuits, this method is unsatisfactory on account of capacity effects and also because of the higher voltages commonly involved.

Electrostatic Ground Detectors. — For single-phase ungrounded systems the simplest form of ground detector consists of two electrostatic voltmeters, each connected between one line wire and the earth. A ground on either wire causes an inequality in the readings of the two meters.

The more common form of ground detector operates as an electrostatic differential voltmeter. Fig. 1 shows diagrammatically the arrangement for a single-phase instrument. The movable vane V is connected to the earth, the fixed plates S_1 and S_2 are connected one to each of the two mains. Vane V will be equally attracted by the two plates unless the insulation resistances of the two line wires to ground are not equal, but will deflect from its normal position to one side or the other when a ground occurs.

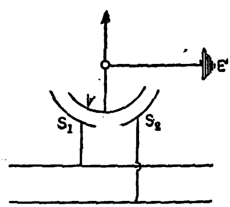

Fig. 1. Single-phase Electrostatic Ground Detector

The three-phase electrostatic ground detector for ungrounded circuits is made in two principal forms. One form consists of three separate elements, each similar to that used in the single-phase instrument, all three elements being in one case but having individual scales. Another form consists of a movable spherical vane, connected to the earth, and three fixed vanes, each of which is connected to one line wire. The movable vane in its normal position is equally distant from each one of the fixed vanes, but, in case of a ground on one line wire, it moves away from the fixed vane which is connected to the line wire on which the ground occurs. The principal parts of this instrument are clearly visible through the glass front of the instrument cover; hence no pointer and scale are needed. Two single-phase detectors will work satisfactorily on three-phase circuits, if the junction point of the two instruments is connected through a condenser to the third line wire.

Voltage Range. — Commercial sizes of electrostatic ground detectors range from 650 volts to 22,000 volts for single-phase circuits, and from 1150 volts to 22,000 volts for three-phase circuits.

Connections. — Electrostatic ground detectors are usually not connected directly to the line wires, especially if the voltage is above 3300. Some types are furnished with special terminal studs containing high-resistance rods of graphite through which the instrument is connected to the line wires. Other types are connected to the circuit through condensers, commonly of tubular form. Although, in this case, the condensers practically insulate the instrument from the line, the leads connecting the detector and the condensers must be treated as high-tension conductors, i.e., they should be properly separated and

far enough from neighboring metal in order that disturbing capacity effects may not be introduced. Therefore, the leads should be fairly short and must not be enclosed in metal conduit.

GROUND DETECTORS FOR NORMALLY GROUNDED SYSTEMS. — The methods outlined above, depending on the variable potential difference between mains and earth, do not apply to earthed systems, e.g., three-wire circuits with grounded neutral, or four-wire, three-phase circuits with grounded neutral. The most usual method for earthed circuits is to connect an ammeter in the earth circuit between the earth plate and the system; hence any leakage current will have to pass through the ammeter. A low-range instrument is desired if slight grounds are to be detected. In order to protect the instrument from excessive currents, an arrangement may be used by which the instrument is short-circuited as soon as the current reaches a certain value, or a resistance may be inserted in the circuit to reduce the current to a safe value. By the second method a short-circuit due to a ground would be suppressed without interruption of service on the line in question. At the same time, however, the pressure on the other line wires with respect to earth would be raised to a higher value.

ARCING-GROUND SUPPRESSORS. — Interruptions to service and damage to apparatus are frequently caused by grounds which tend to persist as arcs, due to the burning away of the conductor. Arcs of this kind may be intermittent, due, for example, to the swinging of the conductor back and forth. Arcing grounds may give rise to disastrous surges in the system. The arcing-ground suppressor, placed on the main bus at the generating station, removes arcs to ground on a line wire by automatically grounding that line wire at the power station, thereby short-circuiting the arc. It is obvious, from the nature of the device, that it cannot be used on earthed systems.

A three-phase arcing-ground suppressor consists of the following parts:

(*a*) Three single-pole, motor-operated, oil switches each connecting one phase of the power house main bus to the ground. These switches are provided with interlocking relays, each of which has three contacts, one of which closes the tripping circuit of its own oil switch while the other two open the tripping circuits of the other two oil switches. Hence it is impossible to have more than one oil switch closed at the same time. For use with overhead systems each switch is equipped with the second-stroke lock device described later. The oil switches are provided with the usual remote-control switches with red and green lights to be placed on the station switchboard.

(*b*) Three single-pole, single-throw disconnecting switches for disconnecting the oil-switches.

(*c*) An electromagnetic selective relay for detecting the grounded phase and operating the proper oil switch. This selective relay is connected to the main bus through three Y-connected transformers of which the neutral on the high-tension side is grounded.

Operation when used with Overhead Lines. — The arcing-ground suppressor is suitable for overhead lines only when metal towers or poles of relatively low resistance are used, as on a wooden pole line the resistance of the pole is liable to prevent sufficient current flowing to ground to reduce the potential sufficiently to operate the phase selective relay.

The operation is as follows: If a ground occurs on one wire in the system, the unbalancing in the potentials of the grounded Y-connected transformers causes the phase selective relay to be operated in such a way that the proper interlocking relay is thereby energized. This closes the corresponding oil switch, thereby grounding the line wire, on which the arcing ground has occurred, through a

metallic circuit. Thus the arcing ground is almost instantly cleared, and the oil switch opens automatically after a fractional part of a second, and remains open, provided the normal state of insulation of the line is reëstablished after the suppression of the arc to ground. Whenever an arc is established or broken, high-frequency oscillations are set up, the duration of which depends on the amount of damping resistance in the circuit (*see Transmission Lines*). In order to eliminate the dangers from such oscillations, a damping resistance placed in the switch pot is thrown in series before the switch rod closes the main contact to ground and after it has opened the main contact.

If the line insulation is permanently broken down by the arc, the line potential will establish a second arc to ground as soon as the metallic ground through the oil switch is opened. The second-stroke lock device then operates; it locks the oil switch as it closes, provided the second closing of the switch occurs immediately after it has been opened. In this case the system remains grounded on one side, and can continue to operate with the metallic ground. After the trouble has been cleared, the oil switch is opened by the attendant.

Operation when used with Underground Cables. — When the arcing-ground suppressor is used for the protection of cables, the second-stroke lock device is omitted, as it is desirable for the oil switch not to be opened after it has once been closed until the feeder has been cleared, the reason being that in a cable the distance of a conductor from the sheath is usually so small that puncture of the insulation produces a permanent fault, and the normal difference of potential is sufficient to reëstablish an arc, even if it were automatically extinguished. The arcing-ground suppressor on cable systems, therefore, minimizes the injury due to a puncture in the cable and prevents the trouble from spreading, and suppresses dangerous high-frequency surges due to arcing grounds. It is not intended to clear short-circuits between line wires.

Location of Arcing-ground Suppressor. — The best location for the arcing-ground suppressor is at the power house, and directly connected to the high-tension bus, where it may be under the immediate observation of the station operator, where a direct-current supply is available, and where the more important switching operations in case of grounds are usually performed.

Costs. — A single-phase electrostatic ground detector costs from $30 to $60, depending upon the voltage, and a three-phase electrostatic ground detector costs from $50 to $150. A three-phase arcing-ground suppressor for voltages from 11,000 to 110,000 costs approximately from $2200 to $6000.

[O. R. SCHURIG.]

GROUNDING OF ELECTRIC CIRCUITS. — (*See also Generators, Alternating-current; Ground Connections; Transformers.*) Some electric circuits are operated insulated, that is with no intentional electrical connection from any point of the circuit to the ground, while others are grounded by one or more conductors provided for the purpose.

Among the considerations influencing the decision of this point are: (1) danger of shock to persons touching the circuit; (2) danger of fire from escaping current, spark, or arc; (3) elimination of electrical oscillations set up in a circuit due to the sudden changes in current resulting from the making and breaking of an arc, usually to ground, usually referred to as an "arcing ground;" such grounds may give abnormal voltages particularly on a-c. circuits where the arc forms and is extinguished twice every cycle; (4) decreased strain on circuit insulation in case of accidental ground; (5) the utilization of the ground and conductors on or in the ground for carrying return currents; (6) the danger of electrolysis and disturbance of telegraph and telephone systems by currents escaping to the ground.

CURRENT (1914) PRACTICE REGARDING GROUNDING. — While the practice of different companies is not consistent with respect to insulating or grounding of various classes of circuits, the following rules probably cover the best practice at the present time.

(1) Low-voltage circuits should be insulated where they are in no way exposed to direct or indirect crossing with other circuits of higher voltage.

(2) Low-voltage circuits should be grounded if there is any danger of crossing with circuits of higher voltage.

(3) Intermediate voltage circuits should be insulated when practicable.

(4) Intermediate voltage circuits if grounded (600-volt railway circuits, for example) should be handled only by experienced people and should be inaccessible to the public.

(5) High-voltage circuits are always dangerous and may be insulated or grounded according to other conditions than safety from shock.

The reasons for the above practice are discussed below.

ELECTRIC SHOCK FROM GROUNDED AND UNGROUNDED CIRCUITS. — Of the various considerations affecting the desirability of grounding a circuit, that of shock is perhaps the most important. (*See also article on Shock, Electric.*) A person touching a circuit at any two points between which there is a difference of potential will receive a shock. The danger or severity of shock from touching simultaneously two line wires of a circuit is not affected by grounding the circuit, but the danger or severity of shock from touching simultaneously either wire and the ground does depend upon whether the circuit is grounded or not.

It should be noted that the sensitiveness of different people to shock varies a great deal and that the severity of a shock depends as much on the surface resistance of the skin (whether dry or wet), and on the parts and organs of the body through which the current passes, as on the voltage. It is therefore impossible to say that any voltage used in practice is so low that under no condition can it give a dangerous shock. However, considering ordinary conditions and the result of a majority of the shocks, circuits of voltages up to and including 220-volts may be considered as not liable to cause a serious shock, whether grounded or ungrounded, and may be referred to as "low-voltage" circuits.

Voltage to Ground of Grounded Circuit. — When a circuit is intentionally grounded, the voltage of the grounded point is made permanently that of the

earth, and the potential of every other point of the circuit becomes fixed with respect to the ground and may be readily calculated (*see Kirchhoff's Laws in index*). Each conductor then carries a definite, predetermined risk, instead of an indefinite risk, which may be nothing or may be very great.

Voltage to Ground of Ungrounded Circuit. — Under normal conditions the average potential of an insulated circuit is the same as that of the ground, the positive parts of a circuit having a potential above and the negative parts below that of the ground. These differences of potential cause the positive and negative wires to be charged like the plates of condensers, the positive wire and earth forming one condenser and the earth and negative wire the other. The positive and negative charges on the wires will be equal and the resultant charge on the earth will be zero in all cases. These condensers are in series and if the circuit is symmetrical the two condensers will have equal capacity. Then the voltage of the positive wire will be as much higher than that of the earth as that of the negative wire is below earth potential. In an unsymmetrical circuit the potentials of the positive and negative wires with respect to earth will be inversely as the capacities.

Current Through Ground Connection. — In case of a ground, either intentional or accidental, the grounded point of the circuit is brought to ground potential and a change is made in the voltage to ground of the positive and negative parts of the circuit, and the resultant charge on the earth is no longer zero. This charge must come by conduction from the circuit and must therefore enter the earth through the ground connection. As long as there is a change in voltage of the wires of the circuit due to the ground connection a current will flow through the ground connection. Such a current is only momentary in the case of a d-c. circuit, but flows as long as the ground continues with alternating currents. See also article on *Capacity and Charging Current.*

The number of amperes which flows through such a ground connection is roughly proportional to the voltage of the system and its electrostatic capacity to ground. The electrostatic capacity is proportional to the extent of the circuit (miles of line). As the miles of line of commercial circuits ordinarily increase about in proportion to the voltage, it follows that the amperes to ground will be about as the square of the voltage of the circuit. The energy which can be liberated at the point of accidental ground will be proportional to this current multiplied by the voltage, that is, will vary as the cube of the voltage. In addition to current due to the capacity to ground there may be a leakage current due to imperfect insulation.

Shock from Single Contact with High-voltage Circuits. — Circuits having a normal line voltage of 11,000 volts or over are generally of sufficient extent (and therefore have sufficient electrostatic capacity) so that a fatal shock may be received from wire to ground, due to the current passing to ground through the body, even though the circuit be otherwise perfectly insulated from ground.

Shock from Intermediate Voltage Circuits. — In general the power available for shock in the current escaping from an insulated circuit to ground is small compared to that in case of contact with the two wires of the circuit. Consequently, there is a class of circuits whose voltages are high enough to give serious or fatal shocks where contact is made with two points of the circuit, but not high enough to give serious (or sometimes even appreciable) shocks from wire to ground when the circuit is ungrounded. These circuits are intermediate between the low-voltage (220-volt) and high-voltage (11,000-volt) circuits above mentioned. This class includes 440- and 550-volt power circuits and usually 1100- and 2200-volt primary circuits, if leakage is small.

Shock from Low-voltage Circuit Crossed (in Contact) With High-voltage Circuit. — When an insulated circuit becomes crossed with a circuit of higher voltage it becomes charged to the voltage of the latter circuit at the point of contact. It becomes practically a part of the higher voltage circuit and is equally dangerous to touch. As its insulation is not designed to stand such abnormally high voltage, there is danger of shock even through the insulation of the conductor.

When a grounded circuit is crossed with one wire of a higher voltage circuit, this wire tends to come to ground potential, and the voltage of the several parts of the low-voltage circuit with respect to the ground remains as before. In cases where a very large amount of current escapes from the high-voltage circuit, this will be appreciably modified by the addition of a voltage due to the resistance or impedance drop in the low-voltage circuit due to the current from the high-voltage circuit from point of contact to ground. If, for example, an outside wire of a three-wire, 110/220-volt, alternating-current secondary circuit, with grounded neutral, should become crossed with a 11,000-volt grounded circuit, a large amount of current may flow into it, which can only escape to the ground after passing through the lamps on one side of the circuit, or through the transformer secondary. The impedance of the path through the lamps and transformer may be high enough so that the voltage of the crossed outside wire of the secondary may be raised to a dangerous voltage above that of the grounded neutral.

Conclusions regarding Effect of Grounding with respect to Shock. — The considerations on which above classification is based lead to the conclusions:

(1) The insulating of low-voltage (under 220 volts) circuits decreases the danger of shock under normal conditions, but as such shocks would rarely be serious, there is little gain in safety through the insulation of the circuit.

(2) The grounding of low-voltage (under 220 volts) circuits greatly decreases the danger of fatal shocks in cases where the low-voltage circuits become crossed with one of higher voltage.

(3) The insulating of intermediate voltage circuits (440 to 2200 volts) greatly decreases the danger of shock under ordinary conditions because most shocks are obtained from touching one conductor, and in such circuits the electrostatic capacity is ordinarily so small that no appreciable current flows to ground.

(4) The grounding of intermediate voltage circuits (440 to 2200 volts) does not greatly decrease the danger of fatal shock in case the circuit becomes crossed with one of higher voltage because the normal voltage of the circuit when grounded is itself dangerous.

(5) Neither the insulating nor grounding of a high-voltage circuit (above 11,000 volts) materially changes the danger of shock which is very great in either case.

DANGER OF FIRE FROM GROUNDED AND UNGROUNDED CIRCUITS. — In general, conditions which diminish the danger of electric shocks also diminish the danger of fire.

The Rules and Requirements of the National Board of Underwriters is the principal authority on the subject of grounding from the standpoint of fire hazard. These rules, given in the National Electrical Code (1911 edition), provide (rule 15) for the grounding of "low-potential systems" (550 volts and under), provided the ground is made on conductor mentioned below:
The rules state that the direct-current system "may be grounded," and that the alternating system "should preferably be grounded." There is no requirement for grounding or insulating of systems having voltages in excess of 550.

	Direct current	Alternating current
2 wire	Not to be grounded	One side for voltage not exceeding 250
3 wire	Neutral only	Neutral only

The rules provide (rule 15) that the grounding of low-potential circuits is only allowed when such circuits are so arranged that under normal conditions of service, there will be no flow of current through the ground connection.

The Committee of the N. E. L. A. on Grounding Secondaries has presented reports at the annual conventions since 1907. These reports discuss the reasons for, and progress in, grounding of secondary distribution circuits.

This committee reported in 1912 the results of a conference with committees from the American Institute of Electrical Engineers, Association of Edison Illuminating Companies and National Inspectors Association, at which it was unanimously voted to recommend to the Electrical Committee of the National Fire Protection Association changes in Rule 15, National Electrical Code (1911 edition), so as to require that transformer secondaries of distributing systems *must* be grounded, provided the maximum difference of potential between the grounded point and any other point in the circuit does not exceed 150 volts, and that where the maximum difference of potential between the grounded point and any other point in the circuit exceeds 150 volts, grounding *may be permitted*.

GROUNDING OF HIGH-VOLTAGE CIRCUITS. — The grounding of low-voltage circuits is governed by considerations of danger of shock and fire, while that of high-voltage circuits is for the purpose of increasing the reliability (continuity of service over the line), or of decreasing the cost of transmission by decreasing or limiting the voltage strain on the line insulator and transformer insulation; see also article on *Generators, Alternating-current* and section on *Transformer Connections* in the article on *Transformers*.

Eliminating Arcing Grounds by Metallic Grounding. — In normally ungrounded high-voltage circuits the current to ground is sometimes sufficient to maintain an arc between one of the wires and a grounded conductor near it but not quite in contact with it, producing a so-called "arcing" ground. Such grounds have been found to produce destructive voltages on the circuit. By metallically grounding the neutral or one wire of the circuit the rise of voltage is reduced. This is perhaps the main reason why many high-voltage circuits are grounded.

Limiting Insulation Strain by Grounding the Neutral. — In high-voltage circuits the cost of insulators is an important element. In an ungrounded circuit each insulator must be large enough to stand full line voltage (between wires), for any phase may become grounded accidentally. Where the neutral of the circuit is grounded the maximum voltage on any insulator can never exceed the normal voltage to ground. The voltages to neutral of a single- or two-phase system is 50 per cent of the voltage between lines, and the voltage to neutral of a three-phase system is 58 per cent of the voltage between lines. A circuit with grounded neutral therefore requires insulators of from 50 to 58 per cent of those for same circuit with insulated neutral, or for the same size insulator the line voltage can be from 73 to 100 per cent higher with grounded neutral than without. These figures neglect the fact that the maximum strain is constant for grounded neutral, and occurs only for a short time at irregular intervals with insulated neutral. In practice the same insulators are usually

used whether the neutral is grounded or not, the factor of safety being higher when the neutral is grounded.

Limiting Short-circuit Current by Resistance.— In a grounded circuit every accidental ground becomes a short-circuit. As such short-circuits may be destructive to generating machinery, the current is sometimes limited by a resistance in the ground connection (usually made at the neutral). The amount of resistance required depends on the per cent of short-circuit current which is permissable. The resistance has, however, the disadvantage that it increases the strain on the insulation, so that as the short-circuit current is reduced, the benefit to the insulation is also reduced. Where the circuit is grounded as a remedy for arcing grounds and no increased factor of safety on the insulator for normal condition of operation is desired, the use of resistance in the ground connection is allowable.

Use of Ground for Return Circuit. — Connections to ground are little used as return paths for the normal current of the circuit, except for railway work. Formerly many 500-volt direct-current power circuits, operated from railway circuits which were necessarily grounded, used the ground as a return circuit, though usually only for small or outlying motors. Such connections may cause electrolysis in underground pipes and arcs, in cases where the pipes or other foreign conductors over which the currents are returning, are broken. Present practice on light and power distribution is to provide complete metallic circuits for all currents which will flow in a circuit under normal operating conditions. Where one conductor is to be intentionally grounded the escape of current into the ground may be prevented by grounding it at only one point, or where, on account of great extent of circuit, grounds on same conductor are necessary at several points, the escape of current will be reduced to a minimum, by making the ground connection on the neutral instead of an outside wire.

[R. A. PHILIP.]

GUTTA-PERCHA. — (*See also Insulating Materials; Telegraph Instruments and Circuits; Wires and Cables, Insulated.*) Gutta-percha is derived from the milky secretion or latex of the bark of certain trees of the order of Sapotaceæ, especially the Dichopsia Gutta, found chiefly in the Straits Settlements and Malaccan Archipelago. The trees are felled immediately after the rainy season, and the gutta or gum collected as it exudes from incisions in the bark. Latex is also extracted from the leaves by digesting them in toluol. However it may be extracted, the latex is boiled in water and it is then ready for export.

The chemical composition of gutta-percha is represented by the formula $C_{10}H_{16}$. It resembles dark brown leather at temperatures between 0° C. and 27° C. At higher temperatures it softens, and at 65° C. it is plastic and capable of being molded or rolled. On cooling it returns to the non-plastic condition.

Gutta-percha oxidizes when exposed to the air, changing from dark brown or black to yellowish grey and becoming brittle.

PREPARATION OF GUTTA-PERCHA INSULATION. — For insulating purposes gutta-percha is shredded and squeezed in warm water. It is then kneaded and strained through fine-wire gauze and rolled into sheets. Its further refinement is carried on differently by various manufacturers, the processes being more or less trade secrets. Like rubber it is applied to the wire either by a tubing machine or by strips. Unlike rubber it is used in the pure state without mixture with minerals. Gutta-percha is less porous than rubber and therefore more waterproof, a quality which makes it the best material for submarine cables. Its specific gravity is just above unity.

SPECIFIC RESISTANCE. — The constant K in the formula

$$M = K \log \frac{D}{d}$$

has the value 900 approximately, at 75° F. after one minute electrification. See also article on *Rubber*.

Temperature Coefficient of Resistance. — The temperature coefficient of resistance of gutta-percha is of the same nature as that of rubber (*see article on Rubber*), i.e.,

$$R_T = R_{75}\epsilon^{(75-T)C},$$

where R_{75} is the resistance at 75° F., R_T the resistance at T° F. and C a constant which varies from 0.065 to 0.085. For values of ϵ^x see *Exponential Functions.*

Effect of Pressure upon Resistance. — Gutta-percha being used principally for submarine cables, the effect of pressure upon its resistance is important. Let R = its resistance at atmospheric pressure, R_p = resistance under pressure of p pound per square inch.
Then

$$R_p = R\,(1 - 0.00023\,p).$$

HEAT AND THERMAL PROPERTIES. — (*See also Temperature and Thermometers; Thermodynamics, Principles of.*)

The following is a brief table of contents of this article:

Heat is said to be added to a body, or the body is said to absorb heat, (1) whenever its temperature rises, (2) whenever it passes from a solid to a liquid state, or (3) whenever it passes from a liquid to a gaseous state; when the reverse of these changes takes place the body is said to lose or to give out heat. A body can also absorb (or give out) heat without any of these changes taking place, provided it gives out (or absorbs) at each instant an amount of energy of some other form equivalent to that absorbed (or given out) as heat. The heat absorbed or given out by a body in virtue of a change in its temperature is called "sensible" heat; heat absorbed or given out in passing from one state to another is called "latent" heat. Experiment shows that heat may be considered as a form of energy.

Symbol for Heat (H). — Both H and Q are commonly used to designate quantity of heat. The symbol H is used throughout this article.

UNITS OF HEAT. — There are several arbitrarily chosen units of heat, viz.,

15° Gram-Calorie or Small Calorie. — The heat necessary to raise the temperature of 1 gram of water from 14.5° C. to 15.5° C. This is the unit commonly employed in scientific work.

Mean Gram-Calorie or Small Calorie. — The $\frac{1}{100}$th part of the heat required to raise the temperature of 1 gram of *water* from 0° C. to 100° C., the latent heat of fusion and boiling not being included. According to Marks and Davis (*Steam Tables and Diagrams, N. Y., 1912*), the 15° calorie and the mean small calorie differ by less than one-tenth of one per cent.

Kilogram-Calorie or Large Calorie. — The heat required to raise the temperature of 1 kilogram of water from 14.5° C. to 15.5° or the $\frac{1}{100}$th part of the heat required to raise the temperature of 1 kilogram of water from 0° C. to 100° C. The relation between the gram-calorie and the kilogram-calorie is then

$$1 \text{ kilogram-calorie} = 1000 \text{ gram-calories.}$$

Ostwald Calorie. — The heat required to raise the temperature of 1 gram of water from 0° C. to 100° C. This unit is frequently used by electrochemists.

$$1 \text{ Ostwald calorie} = 100 \text{ mean gram-calories.}$$

British Thermal Unit (B.t.u.). — The heat required to raise the temperature of 1 pound of water 1° F. There is no general agreement as to *which* degree of temperature shall be used; Peabody uses the degree from 62° F. to 63° F. Marks and Davis define the British thermal unit as the $\frac{1}{180}$th part of the heat required to raise the temperature of 1 pound of water from 32° F. to 212° F. The B.t.u. as defined by Marks and Davis is about 0.13 per cent greater than the B.t.u. as defined by Peabody. Marks and Davis's definition is adopted throughout

this book; the difference between the two is negligible for ordinary practical work. The relation between the B.t.u. and the mean kilogram-calorie is

$$1 \text{ B.t.u.} = 0.25200 \text{ kilogram-calories.}$$

Mechanical Equivalent of Heat. — This is the name given to the experimentally determined conversion factor between any heat unit and any unit of mechanical work; see *Units and Conversion Factors*. The fundamental relation is

$$1 \text{ mean gram-calorie} = 4.1834 \times 10^7 \text{ ergs.}$$

This is the value given by Marks and Davis.

THERMAL CAPACITY AND SPECIFIC HEAT. — The "thermal capacity" of a body is defined as the heat absorbed by the body per unit increase in its temperature, there being during this change in temperature no change of state (e.g., no change from solid to liquid or from liquid to gaseous form or no chemical change) and no transfer of heat energy from the body in question to other bodies. The thermal capacity *per unit mass* of a substance is approximately constant, but increases slightly with increase in temperature; in the case of iron the increase with temperature is quite marked. Calling C the thermal capacity per unit mass of a substance the heat absorbed by a homogeneous mass M when its temperature increases from t_1 to t_2 is

$$H = CM\,(t_2 - t_1)$$

provided C is constant.

The mean thermal capacity per unit mass of water (between 0° C. and 100° C.), when expressed in mean gram-calories per gram per degree centigrade, is numerically equal to unity. The ratio of the thermal capacity per unit mass of any substance to the mean thermal capacity of water is called the "specific heat" of the substance. The specific heat of a substance does not depend upon the units in which the various quantities are measured; its thermal capacity per unit mass does. When heat is expressed in mean gram-calories, mass in grams and temperature in degrees centigrade, the thermal capacity per unit mass is equal to its specific heat; compare with density and specific gravity.

Calculation of Heat Absorbed or Given Out. —

C = specific heat (gram-calories per gram per °C.),
M = mass heated,
$t_2 - t_1$ = rise of temperature.

Then for any set of units the heat absorbed is

$$H = kCM\,(t_2 - t_1),$$

where k has the following values:

VALUES OF k

Unit of heat or energy	Unit of mass	Temperature scale	Value of k
Gram-calorie	Gram	Centigrade	1.000
Kilogram-calorie	Kilogram	Centigrade	1.000
B.t.u	Pound	Centigrade	1.800
B.t.u	Pound	Fahrenheit	1.000
Watt-second (joule)	Gram	Centigrade	4.183
Watt-second (joule)	Pound	Fahrenheit	1054
Kilowatt-hour	Kilogram	Centigrade	1.162×10^{-3}
Kilowatt-hour	Pound	Fahrenheit	2.928×10^{-4}

Values of Specific Heat. — In the table below are given the values of the specific heat for the more common substances used in engineering work. These numbers are also equal to the thermal capacity per unit mass, when mass is expressed in grams, temperature in degrees centigrade and heat in gram-calories.

TABLE I. — SPECIFIC HEAT OF SOME COMMON SUBSTANCES

(From Landolt-Börnstein Tables; see also article on Pyrometers.)

Substance	Temperature, °C.	Specific heat C.	Substance	Temperature, °C.	Specific heat C.
Air (*a*)	–102 to 440	0.237	Lead	17 to 100	0.031
Aluminum	15 to 435	0.236	Manganin (*e*)	18	0.097
Ammonia	23 to 216	0.520	Manganin (*e*)	100	0.100
Antimony	22 to 600	0.052	Marble	0 to 100	0.206
Asbestos	20 to 98	0.195	Mercury	0	0.0335
Bismuth	–79 to 100	0.029	Mercury	100	0.0326
Brass (*b*)	20 to 100	0.092	Mica	20 to 98	0.208
Bronze (*c*)	20 to 100	0.104	Molybdenum	20 to 550	0.072
Carbon (gas carbon)	20 to 1040	0.315	Nickel	0 to 105	0.108
Carbon (graphite)	0 to 3000	0.535	Nitrogen (*a*)	0 to 200	0.244
Carbon dioxide (*a*)	– 78 to 7	0.184	Nitrous oxide (*a*)	13 to 172	0.231
Carbon dioxide (*a*)	0 to 200	0.215	Oxygen (*a*)	20 to 440	0.224
Carbon monoxide (*a*)	23 to 198	0.243	Osmium	19 to 98	0.031
Cement (Portland)	28 to 30	0.271	Palladium	0 to 100	0.059
Chlorine	13 to 202	0.124	Palladium	0 to 1265	0.071
Cobalt	15 to 350	0.109	Paraffine	25 to 30	0.589
Constantan (*d*)	18	0.098	Petroleum	21 to 58	0.511
Constantan (*d*)	100	0.102	Petroleum	18 to 99	0.498
Copper	–188 to 20	0.080	Platinum	0 to 100	0.032
Copper	0 to 100	0.094	Rhodium	10 to 97	0.058
Copper	300	0.098	Silver	0 to 260	0.057
Copper	900	0.126	Steam (*g*)	....	.....
Cork	....	0.485	Steel	20 to 100	0.118
Cotton	0 to 100	0.362	Tantalum	–185 to 20	0.033
Ebonite	....	0.339	Tin	17 to 100	0.056
German silver	0 to 100	0.095	Tungsten	20 to 100	0.034
Glass	0 to 19	0.171	Wax (yellow)	26 to 42	0.820
Glass	56 to 78	0.192	Wood's metal (*f*)	5 to 50	0.035
Gold	0 to 100	0.032	Wool	....	0.393
Hydrogen (*a*)	– 28 to 198	3.41	Zinc	20 to 100	0.093
Ice	– 78 to –18	0.463			
Iridium	0 to 100	0.032			
Iron, cast	18 to 100	0.113			

(*a*) At constant pressure of 1 atmosphere.
(*b*) 60 Cu + 40 Zn.
(*c*) 88.7 Cu + 11.3 Al.
(*d*) 60 Cu + 40 Ni.
(*e*) 84 Cu + 4Ni + 12 Mn.
(*f*) 25.85 Pb + 6.99 Cd + 52.43 Bi + 14.73 Sn.
(*g*) See article on *Steam*.

Specific Heats at Constant Volume and Constant Pressure.—In general, when a body absorbs heat an expansion (contraction in a few cases) results and the body does work on whatever opposes this expansion, part of the heat absorbed being thus converted into mechanical work; see *Thermodynamics, Principles of*. In the case of solids and liquids the external work done is practically negligible. In the case of gases and vapors, however, the external work done is appreciable. The specific heat of a gas or vapor when kept at constant volume, so that it can do no external work, is called the specific heat at constant volume, and is usually designated by the symbol C_v. The specific heat of a gas or vapor when it is allowed to expand at constant pressure is called the specific heat at constant pressure, and is usually designated by the symbol C_p. The ratio

$$\gamma = \frac{C_p}{C_v}$$

has very nearly the same value, 1.40 approximately, for all ordinary (diatomic) gases; see Table II.

TABLE II.—VALUE OF $\gamma = \frac{C_p}{C_v}$ FOR SOME GASES AT ATMOSPHERIC PRESSURE

(*From Landolt-Börnstein Tables.*)

Gas	Temperature, °C.	$\gamma = \frac{C_p}{C_v}$	Gas	Temperature, °C.	$\gamma = \frac{C_p}{C_v}$
Air	−181	1.34	Chlorine	20–340	1.32
Air	0	1.40	Hydrogen	......	1.40
Air	900	1.39	Nitrogen	......	1.40
Ammonia	0–100	1.30	Nitrous oxide	0–100	1.29
Carbon dioxide	0–100	1.30	Oxygen	......	1.40
Carbon monoxide	0–100	1.40			

Recalescence.—When heat is supplied at a uniform rate to a piece of iron or steel it is found that the rate of increase of temperature gradually increases (i.e., uniform increase of specific heat) until a certain temperature is reached at which the rise of temperature is suddenly and in most cases greatly retarded or even completely arrested. The reverse of this effect occurs when the sample is cooled down from a temperature above this point, and under certain conditions there occurs a spontaneous reheating during the cooling. Any point at which there is an abrupt change in the slope of a heating or cooling curve is called a "recalescence" point; there is a very marked recalescence point for most irons and steels and also one or more points at which the same effect occurs but to a lesser degree. The major recalescence point of ordinary iron or steel is usually between 750° C. and 850° C.

MELTING OR FREEZING POINT AND HEAT OF FUSION.—Certain chemically simple substances when heated to a definite temperature pass from the solid to the liquid state with no increase in temperature during this change in state, provided the solid and liquid are kept thoroughly mixed, but the change is accompanied by a considerable absorption of heat. The temperature at which the change takes place is called the melting point or freezing point (the reverse change takes place at the same temperature), and the heat

absorbed per unit mass is called the heat of fusion or heat of liquefaction; this same amount of heat is given out when the body solidifies. In the case of many substances, however, there is no definite melting point, the change from one state to the other being gradual; such substances begin to melt at a lower temperature than that at which solidification begins during cooling. The melting points and heats of fusion for some common substances are given in Table III. The values printed in bold face type are recommended by the Bureau of Standards as suitable for pyrometer calibration.

Freezing Mixtures. — The addition of an impurity to a liquid lowers the freezing point, a common example of which is the lowering of the freezing point of water by the addition of salt. Also, when certain substances go into solution the temperature of the solution is lowered. Some common freezing mixtures are the following, taken from *Hütte.*

FREEZING MIXTURES

Mixture	Parts by weight	Decrease of temp., °C. From	Decrease of temp., °C. To	Parts by weight	Decrease of temp., °C. From	Decrease of temp., °C. To
Snow Common salt (NaCl)	3 1	0	−17.7	1 1	0	−18
Snow Calcium chloride ($CaCl_2$)	2 3	0	−33	1 2	0	−42
Snow Potassium hydrate (KOH)	3 4	0	−37	..	..	....
Water Ammonium nitrate (NH_4NO_3)	1 1	+10	−16	..	..	....
Water Sal ammoniac (NH_4Cl) Saltpeter (KNO_3)	16 5 5	+10	−12	1 1 1	+8	−24

VAPORIZATION. — Above the surface of any liquid there always exists a certain amount of the substance in a gaseous form, i.e., as a vapor, the amount of which depends upon the nature of the substance and upon the temperature and the pressure in the space occupied by the vapor and such other gases (e.g., air) as may be present. In the case of a simple liquid evaporating into a space from which all other gases and vapors have been removed, the evaporation ceases when a definite pressure is established in this space, this equilibrium pressure depending only upon the temperature at which this space is maintained. This statement is true only when there always remains some unevaporated liquid; if all the liquid evaporates, then the equilibrium pressure also depends upon the mass of the vapor and the space which it occupies; as long as some liquid remains, the equilibrium pressure depends only upon the temperature and is independent of the volume of the space and the mass of the vapor which occupies it. This equilibrium pressure for any given temperature is called the (normal) "vapor pressure" or "vapor tension" at that temperature, and the vapor is said to be "saturated," i.e., each unit volume of the space contains the greatest possible mass of vapor which can occupy it at this particular temperature. Diminishing the volume of the space (at constant temperature) occupied by a saturated vapor causes some of the vapor to condense, and what is left remains saturated at the same pressure and temperature. Increasing the volume of the space (at constant temperature) causes more of the liquid to evaporate and the vapor still remains saturated at the same pressure and temperature, provided always that some liquid is left.

Boiling Point and Heat of Vaporization. — The temperature corresponding to any given pressure at which a vapor is completely saturated is called the "boiling point" of the liquid at this pressure. The temperature of a liquid which is "boiling" in the ordinary sense of the term is in general greater than the temperature of the saturated vapor above it, since the vapor in the bubbles formed is under a greater pressure than the vapor above the surface. The quantity of heat required to convert unit mass of a liquid into vapor at a given pressure is called the heat of vaporization or heat of evaporation of the liquid at this pressure; the same quantity of heat is given out by unit mass of the vapor when it condenses at this same pressure. The boiling points and heats of vaporization generally given are for normal atmospheric pressure, viz., 76 cm.

mercury. Values of these two quantities for some common substances are given in Table III.

Unsaturated or Superheated Vapors; Gases.—When the pressure exerted by a vapor against the walls of the containing vessel is less than the saturation or "normal" vapor pressure, the vapor is said to be unsaturated or superheated. This state of affairs may be brought about either (1) by increasing the volume of a saturated vapor when there is no longer any liquid left to evaporate, keeping the temperature constant, or (2) by raising the temperature of such a saturated vapor, keeping the pressure constant, or (3) by a proper combination of (1) and (2). The ordinary so-called "permanent" gases are superheated vapors, the degree of superheat being very great. The distinction ordinarily made between a gas and a vapor is that a gas is far removed, with respect to temperature and pressure, from the saturated state, whereas a comparatively small increase in the pressure or decrease in the temperature of a vapor will saturate it.

Laws of Perfect Gases. — Ordinary gases, such as air and superheated vapors (the greater the superheat the more nearly do the relations hold), are found to obey *approximately* the following "law,"

$$pV = \frac{MRT}{\mu},$$

where p = absolute pressure of the gas,
V = volume occupied by it,
M = mass of the gas,
T = absolute temperature; see Table V below,
μ = molecular weight of the gas;* see Table IV below,
R = a constant for all gases, called the "gas constant," whose value depends only upon the units in which the various quantities are expressed; see Table V.

TABLE IV. — MOLECULAR WEIGHTS OF GASES

Gas	μ	Gas	μ
Air (75.5 N+23.2 O+1.3 A)...	28.98	Chlorine (Cl_2)...............	70.92
Acetylene (C_2H_2)	26.02	Hydrogen (H_2)...............	2.016
Ammonia (NH_3)............	17.03	Nitrogen (N_2)...............	28.02
Carbon dioxide (CO_2).......	44.00	Nitrous oxide (N_2O).........	44.02
Carbon monoxide (CO).....	28.00	Oxygen (O_2).................	32.00

The above relation can be deduced from purely thermodynamic relations (*see Thermodynamics, Principles of*) on the assumptions: (1) that the product pV at constant temperature is a constant for any particular gas (*Boyle's or Mariotte's Law*), (2) that the intrinsic energy per unit mass of a gas depends only on its temperature, being independent of the volume and nature of the gas (*Joule's Gas Law*), and (3) that at constant volume the specific heat of the gas is inde-

* For a mixture (without chemical reaction) of perfect gases of different molecular weights, the equivalent molecular weight of the mixture is

$$\mu = \frac{M_1 + M_2 + M_3 + \ldots}{\frac{M_1}{\mu_1} + \frac{M_2}{\mu_2} + \frac{M_3}{\mu_3} + \ldots},$$

where M_1, M_2, M_3, etc., are the masses of the individual constituents and μ_1, μ_2, μ_3, etc., their molecular weights.

pendent of its temperature. A gas which satisfies the above conditions is called a "perfect" gas; all ordinary gases and highly superheated vapors satisfy these conditions approximately.

As a consequence of the above law the following relations must hold for a perfect gas; they also apply approximately to ordinary gases. In addition to the symbols above, let

C_v = specific heat at constant volume,
C_p = specific heat at constant pressure,
$\gamma = \frac{C_p}{C_v}$,
W_{12} = work done on the gas when its pressure changes from p_1 to p_2
H_{12} = heat absorbed by the gas when its pressure changes from p_1 to p_2
J = mechanical equivalent of heat.

Then for a perfect gas, for an *isothermal change*, i.e., a change at constant temperature ($T_1 = T_2$)

$$W_{12} = p_1 V_1 \log_e \left(\frac{p_2}{p_1}\right), \quad H_{12} = \frac{W_{12}}{J},$$

and for an *adiabatic change*, i.e., no heat passes in or out of the gas ($H_{12} = 0$)

$$\frac{p_1}{p_2} = \left(\frac{V_2}{V_1}\right)^{\gamma}, \quad \frac{T_1}{T_2} = \left(\frac{V_2}{V_1}\right)^{\gamma-1} = \left(\frac{p_1}{p_2}\right)^{\frac{\gamma-1}{\gamma}}.$$

$$W_{12} = JC_v\,(t_1 - t_2) = \frac{p_1 V_1\,(t_1 - t_2)}{T_1\,(\gamma - 1)}.$$

Any one of the four sets of units given in the following table (or any other *consistent* set) may be used in these formulas.

TABLE V.—VALUES OF THE GAS CONSTANT R AND MECHANICAL EQUIVALENT J

Notation	Units and constants			
M=mass	kg.	grams	lb.	gram

Gas Saturated with Vapor.—Experience shows that when a substance evaporates into a space already occupied by a gas (e.g., water evaporating into the atmosphere), evaporation ceases for any given temperature when a definite pressure (depending upon the temperature and the nature of the vapor and the gas) is established in the mixture; or, if the pressure and temperature are maintained constant, then evaporation ceases when a definite amount of vapor has been produced. When a mixture of a gas and a vapor contains this maximum mass of vapor per unit volume of the mixture, the gas is said to be saturated with the vapor. Such a mixture may contain less of the vapor per unit

volume than this maximum amount; the ratio of the mass of vapor per unit volume actually present to the maximum possible mass per unit volume at any given pressure and temperature is called the "relative humidity" of the mixture. The relative humidity of a mixture (e.g., air and water vapor) can be determined by the use of a dry- and wet- bulb thermometer. (*See the Hygrometric Tables of the U.S. Weather Bureau.*)

Calculation of the Amount of Moisture in Saturated Air.— The relations given below are approximate but sufficiently accurate for practical work; they apply to a mixture of any gas and vapor which do not act chemically upon each other. Let

t = temperature of the mixture,
p = absolute pressure of the mixture,
T = absolute temperature corresponding to t, see Table V above,
R = gas constant, from Table V above,
29 = molecular weight of air; see Table IV above,
p_w = normal vapor pressure of steam at the temperature t, to be taken directly from steam tables, see article on *Steam*,
δ_w = mass of unit volume of steam at the pressure p_w; also to be taken from steam tables,
$\delta_a = \dfrac{29\,(p - p_w)}{RT}$ = mass of unit volume of air at the pressure $(p - p_w)$ and temperature t,
$\delta_m = \delta_w + \delta_a$ = mass of unit volume of the mixture.

Example. — (1) What is the weight (mass) in lb. per cu. ft. of air saturated at normal atmospheric pressure (14.70 lb. per sq. in.) with water vapor at 100° F.? (2) What is the weight in lb. of the water contained in 1 cu. ft. of the mixture? From the above formulas $p = 14.70 \times 144$ lb. per sq. ft.; $p_w = 0.946 \times 144$ lb. per sq. ft.; $\delta_w = 0.002851$ lb. per cu. ft.; $T = 460 + 100 = 560°$ F.; $R = 1547$; $\delta_a = \dfrac{29\,(14.7 - 0.946) \times 144}{1547 \times 560} = 0.06630$ lb. per cu. ft.; $\delta_m = 0.002851 + 0.06630 = 0.06915$ lb. per cu. ft. Answer: The mixture weighs 0.06915 lb. per cu. ft. and contains 0.002851 lb. of moisture per cu. ft.

Dalton's Law; Partial Pressures. — The above calculation is based upon the experimentally determined relation, known as Dalton's Law, that, in a mixture of several gases or vapors which do not react chemically upon each other, the total pressure for a given volume of the mixture is approximately equal to the sum of the individual pressures which each gas or vapor would produce if it alone filled this volume. For example, if a mixture of three gases or vapors A, B and C fill, when mixed, a volume V and produce a pressure p, then if the gas or vapor A by itself would exert a pressure p_a when it alone occupied this volume V, and gas B by itself would exert a pressure p_b when it alone occupied this volume V, and similarly for gas or vapor C, then

$$p = p_a + p_b + p_c.$$

The pressures p_a, p_b and p_c are called "partial" pressures. Dalton's Law holds only approximately, but is sufficiently accurate for most practical calculations.

Sublimation. — When a substance passes directly from a solid to a gaseous state the phenomenon is called sublimation. A common instance of this is the sublimation of solid carbonic acid, which passes from solid to gaseous form at atmospheric pressure at a temperature of − 79° C. and absorbs 140 gram-calories per gram or kilogram-calories per kilogram.

TRANSFER OF HEAT. — When a body is at a higher temperature than the surrounding bodies, energy is transferred from the hotter to the colder

bodies, as is manifested by the changes in temperature or state which tend to, or actually do, take place, even though the intervening space is entirely void of matter. The energy thus transferred from one body to another through empty space is called "radiant energy," or "radiant heat," and is similar in nature to the energy radiated in the form of light waves and electromagnetic waves. The waves of radiant heat have a length greater than that of light waves and less than that of the ordinary electromagnetic waves used in wireless telegraphy. Radiant heat is absorbed by, transmitted through and reflected by, ordinary matter in much the same way that light waves are absorbed, transmitted and reflected. Matter which is transparent to light waves, however, may be practically opaque to heat waves; e.g., water absorbs practically all the heat waves which fall upon it.

When a hot and a cold body are separated by a fluid which is free to circulate, heat is transferred from the hot to the cold body by currents of the fluid itself flowing from one to the other; similarly, all parts of a fluid which is being heated quickly come to approximately the same temperature. This transfer of heat by currents of the fluid itself is called "convection."

In the case of a hot and a cold body separated by a solid the transfer of heat, which may be very rapid, particularly when the separating medium is a metal, is probably due to an extremely rapid to-and-fro motion of the molecules which constitute the medium. In any event, the process is essentially different from the transfer of heat either by radiation or by convection; it is described by the term "conduction" of heat.

Radiation, Absorption and Reflection of Heat. — The rate at which a hotter body radiates heat, and a colder body absorbs heat, depends upon the state of the surfaces of the bodies as well as on their temperatures. The rate of radiation and of absorption are increased by darkness and roughness of the surfaces of the bodies, and diminished by smoothness and polish. For this reason the covering of steam pipes and boilers should be smooth and of a light color; uncovered pipes and steam-cylinder covers should be polished.

The heat radiated by a body at a given temperature T to surrounding bodies at a lower temperature is equal to the heat which this body would absorb at this same temperature T from surrounding bodies at a higher temperature. When a given quantity of radiant heat strikes a body, only part of the heat is, as a rule, absorbed, the rest being reflected.

Let H_i be the incident heat, H_r the reflected heat, and H_a the absorbed heat, at temperature t, and let H_e be the heat which the body would emit at this same temperature to bodies at a lower temperature; then

$$H_i = H_r + H_a,$$
$$H_a = H_e.$$

Definition of "Black Body"; Stefan-Boltzman Law. — A "black body" is defined as one that absorbs all radiations falling upon it, neither reflecting nor transmitting any. The radiation of such a body is a function of the temperature alone, and is identical with the radiation inside an inclosure all parts of which have the same temperature. By heating the walls of an inclosure as uniformly as possible and observing the radiation through a very small opening, a practical realization of a black body is obtained.

The radiation from such a body is found to obey the following law

$$E = K\,(T^4 - T_0^4)\,At,$$

where E is the total energy radiated in time t from such a body at an *absolute* temperature T to surrounding bodies maintained at an *absolute* temperature T_0. A is the area of the surface of the body and K is a constant. This relation

is known as the Stefan-Boltzman Law. When the *absolute* temperature T is over three times the absolute temperature T_0, this relation may be written

$$E = KT^4At.$$

The mean of the best determinations of the value of K is 1.28×10^{-12} when E is expressed in gram-calories and T in centigrade degrees. For other units K has the following values

VALUES OF K

Unit of energy (E)	Unit of area (A)	Unit of time (t)	Temperature scale	Absolute zero	K=
Gram-calorie.......	sq. cm.	second	Centigrade	−273	1.28×10^{-12}
Kg-calories	sq. meter	hour	Centigrade	−273	4.61×10^{-8}
B.t.u..............	sq. ft.	hour	Fahrenheit	−460	1.62×10^{-9}
Watt-seconds.......	sq. cm.	second	Centigrade	−273	5.35×10^{-12}
Kw-hr	sq. in.	hour	Centigrade	−273	3.45×10^{-14}

Radiating and Reflecting Powers. — The ratio of the heat radiated per unit area by any surface at a given temperature t to the heat radiated per unit area by an absolutely black surface at this same temperature t is called the radiating power of the surface at that temperature. The difference between this ratio and unity is a measure of the heat which would be reflected by this surface at the same temperature, and is defined as the reflecting power of the surface. The radiating power of a surface depends upon the temperature of the surface; at very high temperatures the radiating power of every surface approaches the value of unity, i.e., at high temperatures the total energy radiated by any surface approaches in value the total energy radiated by an absolutely black body. The following table from Kent's *Mechanical Engineer's Pocketbook* gives the approximate value of the radiating power of some common surfaces at ordinary temperatures.

TABLE VI. — APPROXIMATE RADIATING AND ABSORBING POWERS

Surface	Radiating or absorbing power	Surface	Radiating or absorbing power
Lampblack..................	100	Zinc, polished..............	19
Water......................	100	Steel, polished..............	17
Carbonate of lead..........	100	Platinum, polished..........	24
Writing-paper..............	98	Platinum in sheet...........	17
Ivory, jet, marble..........	93–98	Tin.........................	15
Ordinary glass.............	90	Brass, cast, dead polished...	11
Ice........................	85	Brass, bright polished.......	7
Gum lac....................	72	Copper, varnished...........	14
Silver-leaf on glass..........	27	Copper, hammered..........	7
Cast iron, bright polished...	25	Gold, plated................	5
Mercury, about.............	23	Gold on polished steel.......	3
Wrought iron, polished......	23	Silver, polished bright.......	3

Oiling a polished surface may increase its radiating power from 2 to 3 times, but oiling does not seriously affect the radiating power of a rough surface.

Conduction of Heat. — Whenever a difference of temperature is maintained between any two parts of the same body there is a transfer of heat from the hotter to the colder part by the process described by the term "conduction," as distinguished from radiation and convection; also when two bodies at different temperatures are in direct contact there is a transfer of heat across the surface contact from the hotter to the colder body, the process being similar in nature to the conduction of heat from a hotter to a colder part of the same body. The first type of conduction is called "internal" conduction; the second type "external" conduction.

Internal Conduction. — Consider a flat layer *within* a substance, the two sides of the layer being parallel and its thickness small compared with its area. Let one side of this be maintained at a constant temperature T, the same at all points of this surface, and the other side of the layer be maintained at a constant temperature T_1; let A be the area of the layer (i.e., of one of its flat surfaces) and x the thickness of the layer. Then the amount of heat transferred through the layer in time t is,

$$H = \frac{K A (T - T_1) t}{x},$$

where K, called the "thermal conductivity," is approximately a constant for a given material, and is independent of the temperature difference $T - T_1$, when this difference is small; K is not constant, however, for wide temperature variations. Values of K are given in Tables VII and VIII. The reciprocal of the thermal conductivity, viz., $\rho = 1/K$, is called the thermal resistivity.

The values of K given in the tables below are the values of this factor when H is expressed in gram-calories, A in sq. cm., x in cm., $(T - T_1)$ in ° C., and t in seconds; i.e., K is the number of gram-calories transmitted per second through a cube 1 cm. on each edge when a difference of temperature of 1° C. is maintained between opposite faces of this cube. For other units the value of K as given should be multiplied by the factor noted in the following table:

Unit of heat	Unit of area	Unit of thickness	Unit of time	Unit of temp. diff.	Multiply K by
Gram-calorie	sq. cm.	cm.	second	° C.	1.000
Kg-calorie	sq. m.	cm.	hour	° C.	3.600×10^4
B.t.u.	sq. ft.	inch	hour	° F.	2902
Watt-seconds	sq. cm.	cm.	second	° C.	4.183
Watt-seconds	sq. ft.	inch	second	° F.	850.8
Kw-hr.	sq. m.	cm.	hour	° C.	41.83
Kw-hr.	sq. ft.	inch	hour	° F.	0.8508

Conduction through Other than Thin Layers. — The formula for H given above is applicable only *when the lines of flow are straight and perpendicular to A and the temperatures T and T_1 are temperatures of the surfaces of the substance itself*, not the temperatures of a fluid, for example, in contact with these surfaces. Failure to take these facts into consideration accounts for some of the inconsistencies in the reported values of thermal conductivity from tests. To calculate the flow of heat in other cases, formulas analogous to those for electric resistance and conductance must be employed; see ***Resistance and Conductance.***

Temperature Coefficient of the Internal Thermal Conductivity.—In the case of metals the variation of the internal thermal conductivity with temperature may be expressed with a fair degree of approximation by the relation

$$K = K_0 (1 + at),$$

where K_0 is the conductivity at 0° C., say, and K is the conductivity at any other temperature of t °C., and a is a constant. The coefficient a may be either positive or negative; its value for some of the common metals is given in Table VII.

Values of the Internal Thermal Conductivity (K) of Materials.—In the following tables, VII and VIII, are given the thermal conductivity of certain common non-metallic and metallic substances respectively. The data are from the following sources: Landolt-Börnstein, *Physikalisch-Chemische Tabellen*, 1912; Nusselt, W., *Zeit. Ver. Deutch. Eng.*, June, 1908; Hering, Carl, *Trans., A.I.E.E.*, 1910; Randolph, C. P., *Trans. Am. Electrochem. Society*, 1912; Ordway, *Trans. Am. Soc. Mech. Eng.*, 1884-85; Coleman, J. J., *Engineering*, Sept. 5, 1884; Scott, H. G., *Power*, 1902; Wolff, *Jour. Frank. Inst.*, 1893; Peclet, *Practical Treatise on Heat*; *Met. & Chem. Eng.*, Feb. 1909, p. 72; Brill, G. M., *Trans. Am. Soc. Mech. Eng.*, Vol. 16, p. 827; *Smithsonian Physical Tables*.

External Thermal Conduction — Thermal "Contact" Resistance. —A "current" or flow of heat in passing from one substance to another, e.g., from air to a metal or from water to a metal and vice versa, experiences a thermal resistance analogous to the contact resistance at the junction of two dissimilar conductors, e.g., a carbon brush on a commutator. Data on this point are meagre. For thin plates Peclet gives the following formula for small temperature differences,

$$R_c = \frac{1}{A[1 + B(T - T_1)]},$$

where R_c represents the *total* contact resistance for *both* surfaces *per unit area* perpendicular to the direction of flow, T and T_1 the temperatures of the air or water in contact with the two sides of the plate, and A and B are coefficients having the following values when the quantities involved are expressed in B.t.u.-hour-sq. ft.-Fahrenheit units.

VALUES OF A AND B

	A	B
Air on both sides:		
Polished metal surfaces	0.90	0.0028
Glassy or varnished surfaces	1.34	0.0037
Dull metallic surfaces	1.58	0.0037
Lampblack	1.78	......
Water on both sides:		
Metal surfaces	8.8	0.058

For a large difference of temperature, the term $B(T - T_1)$ becomes large in comparison with unity, whence the total flow of heat H from the fire box to the water through an area S is

$$H = \frac{(T - T_1)^2 S}{a}.$$

Results from tests on boiler plates and tubes give values of a ranging from 160 to over 200, when the quantities involved are expressed in B.t.u.-hour-sq. ft.-Fahrenheit units.

Total Thermal Resistance of a Thin Plate. — Let x be the thickness of the plate, S the area of its surface, T and T_1 the temperatures of the *fluid* in contact with the two surfaces of the plate, ρ the internal thermal resistivity, and r_c and r_c' the thermal contact resistances per unit area between the fluid and the surface of the plate on the two sides respectively. Then the total thermal resistance from fluid to fluid is

$$R = \frac{(r_c + r_c' + \rho x)}{S}$$

and the total flow of heat from fluid to fluid in time t is

$$H = \frac{(T - T_1)t}{R} = \frac{(T - T_1)St}{r_c + r_c' + \rho x}.$$

For boiler plates and tubes with a large difference of temperature between the fire box and the water, the term ρx is small, and $r_c + r_c' = \frac{a}{T - T_1}$, where $a = 1/AB$ is approximately a constant, as noted above.

EXPANSION DUE TO HEATING. — Most substances expand when heated, but water between 0° degrees and 4° C., quartz glass below − 84° C. and a few other substances contract with increase of temperature. When the temperature of a solid is changed by rapid cooling, slow changes in its dimensions continue long after it has attained the same uniform temperature throughout. This effect, which is particularly marked in glass, is known as "thermal hysteresis." It can be largely eliminated by prolonged heating at a high temperature followed by a very gradual cooling, i.e., by annealing.

The volume of a physically homogeneous substance which is not subjected to any treatment causing more or less permanent changes in its structure, is a definite function of its temperature and the pressure or tension in it. In general, under constant pressure or tension the amount of expansion caused by a given change in temperature depends upon both the material of the body and its initial temperature.

Coefficient of Expansion of Gases. — In the case of gases, however, there is a remarkable uniformity, all the so-called permanent gases expanding about $\frac{1}{273}$ part of their *initial volume at 0° C.* per degree centigrade increase of temperature, irrespective of the pressure, provided this remains constant throughout. That is, for any of the ordinary gases,

$$V = V_0\left(1 + \frac{t_c}{273}\right),$$

where V_0 is the volume at 0° C., and V the volume at any other temperature t_c° C., the pressure being the same at both temperatures. If the temperature is expressed in Fahrenheit degrees and V_0 is the volume at 0° F., then

$$V = V_0\left(1 + \frac{t_f}{460}\right).$$

Note that − 273 and − 460 are the absolute zeros on the centigrade and Fahrenheit scales respectively.

Coefficients of Linear Expansion of Liquids and Solids. — Let l_0 be length of a rod, or of column of liquid, at any standard temperature, say 0° C., and l be the length at any other temperature t. Then the exact relation between l and l_0 may be expressed as a series of the form

$$l = l_0\,(1 + at + bt^2 + \ldots),$$

where a, b, etc., are constant coefficients for any given material and *fixed reference temperature*. As a rule the coefficients of the powers of t above the first are much smaller than the first coefficient, and for small ranges of temperature the approximate formula

$$l = l_0\,(1 + at)$$

is usually employed. The coefficient a in this formula is practically a constant for any range of temperature not exceeding 100° C.; it is sometimes called the "mean coefficient of linear expansion" between the limits of temperature chosen. For example, between 0° C. and 100° C., the mean coefficient of linear expansion is defined by the relation

$$a_0 = \frac{l_{100} - l_0}{100\, l_0},$$

where $l_{100} - l_0$ is equal to the change in length produced by increasing the temperature from 0° C., to 100° C.

It should be noted that for each value of the standard or reference temperature a different value of a must be used. For example, if a rod has a length l_1

TABLE IX. — COEFFICIENTS OF LINEAR EXPANSION

$l = l_0 (1 + at + bt^2)$, temperature in °C.*
a_{20} = "true" coefficient at 20°C.

* When the temperature is expressed in Fahrenheit degrees, the formulas become

$$l = l_{32}\left[1 + \frac{a(t_f - 32)}{1.8} + \frac{b\,(t_f - 32)^2}{3.24}\right],$$

$$a_{68} = \frac{a_{20}}{1.8},$$

where a, b and a_{20} have the values given in the above table.

at t_1 degrees and a length l at t degrees, and a_0 is the mean coefficient of linear expansion referred to 0° C., then $l_1 = l_0(1 + a_1t_1)$ and $l = l_0(1 + a_0t)$, whence

$$l = l_1[1 + a_1(t - t_1)],$$

where

$$a_1 = a_0/(1 + a_0t_1).$$

If t_1 is so large that a_0t_1 is appreciable compared with unity then a_1 is not equal to a_0.

True Coefficient of Linear Expansion. — The "true" coefficient of linear expansion at any temperature t is defined as the *rate* of increase of length with increase in temperature divided by the length at this temperature t, or

$$a = \frac{1}{l} \cdot \frac{dl}{dt}.$$

The "true" coefficient a_t any temperature depends on the temperature.

Coefficients of Cubical Expansion of Liquids and Solids. — The volume or cubical expansion of liquids and solids may be expressed in exactly the same manner as the linear expansion, viz.,

$$V = V_0(1 + \alpha t + \beta t^2 + \ldots)$$

or approximately

$$V = V_0(1 + \alpha t),$$

and the true coefficient at any temperature t is defined as

$$\alpha_t = \frac{1}{V}\frac{dV}{dt},$$

where V and V_0 are the volumes at t degrees and at the reference temperature respectively.

As a first approximation, when the coefficient of linear expansion is small and the temperature rise not excessive, the volume coefficient may be taken equal to 3 times the linear coefficient.

A few volume coefficients, determined from direct experiment, are given in Table X. For Water see article on *Weights of Materials.*

TABLE X. — COEFFICIENTS OF CUBICAL EXPANSION

$V = V_0(1 + \alpha t + \beta t^2)$, temperatures in ° C.

FLASH POINT OF OILS.—The flash point of an oil is the temperature to which the oil must be raised before the vapor immediately above it will take fire upon the application of a flame. This temperature depends to an appreciable extent upon the size of the flame, the method of applying it, and the shape and dimensions of the containing vessel; see *Oil, Transformer*. The following values of the flash point for various oils are taken from J. Lewkowitisch, *Chemical Technology and Analysis of Oils, Fats and Waxes*.

TABLE XI.—FLASH POINT OF OILS

Oils	Spec. grav. at 60° F.	Flash point ° F.
Mineral oils:		
Refined American	0.875 to 0.920	325 to 425
Refined Russian	0.895 to 0.915	300 to 425
Scotch	0.875 to 0.895	300 to 350
Natural (dark) American	0.880 to 0.895	325 to 425
Natural (dark) Russian	0.910 to 0.915	250 to 300
Natural filtered American	0.885 to 0.905	450 to 575
Animal oils:		
Sperm	0.8804 to 0.8807	446 to 457
Lard	0.9172	494
Tallow	0.951	265
Neat's foot	0.9178	470
White whale	0.9207	476

Olive	0.914	305
Rape, crude	0.920	265
Rape, refined	0.911	305

HEATS OF FORMATION, COMBUSTION AND SOLUTION.*—When two or more substances react chemically heat is generally either given out or absorbed. When heat is given out the reaction is called "exothermic" and when heat is absorbed the reaction is called "endothermic." The following tables give the heats of reaction for some of the more important industrial processes; see *Landolt-Börnstein's Tables* for more complete tables. A minus sign indicates an endothermic reaction; i.e., an absorption of heat. When two values are given these refer to independent measurements.

The values given are the total amounts of heat in kilogram-calories given out or absorbed per mol (*see Electrochemistry, Principles of*) of the product, starting with the proportions of the reacting substances represented by the left-hand member of the reaction equation, the temperature at the beginning and at the end of the reaction being the same, i.e., room temperature. For example, starting with 1 gram-atom of oxygen (16 kilograms, say) and 1 gram-atom of calcium (40.07 kilograms) both at room temperature, then the net amount of heat given out in the formation of one mol ($16 + 40.07 = 56.07$ kilograms) of calcium oxide when its temperature is brought back to room temperature is 130.9 kilogram-calories or 2.33 kilogram-calories per kilogram of calcium oxide.

* By M. De K. Thompson.

TABLE XII. — HEATS OF FORMATION OF IMPORTANT COMPOUNDS

BIBLIOGRAPHY. — Preston, T., *The Theory of Heat*, London, 1904; Burgess and Le Chatelier, *Measurement of High Temperatures*, New York, 1912; Landolt-Börnstein-Roth, *Physikalisch-Chemische Tabellen*, Berlin, 1912; *Smithsonian Physical Tables*, Wash., 1910.

[H. PENDER and R. G. HUDSON.]

HEATING OF BUILDINGS. — (*See also Railways, Energy Requirements for.*) The problem of determining the amount of heat necessary to maintain a room at a given temperature above the out-door temperature resolves itself into the determination of the amount of heat radiated through the walls and the amount of heat necessary to raise the incoming ventilating air to the temperature of the air in the room.

HEAT REQUIRED TO WARM INCOMING AIR. — Authorities differ as to the amount of air required for ventilating purposes, but a commonly accepted figure is 30 cubic feet of air per person per minute, or 1800 cubic feet per person per hour. 1/56 B.t.u. is required to heat 1 cu. ft. of air 1° F. Let

t = temperature of incoming air, ° F.,
T = temperature of room, ° F.,
N = number of people in room.

Then, assuming 1800 cubic feet of air per person, the B.t.u. per hour required to raise the temperature of the incoming air to the room temperature is

$$H_A = 32.1\,N\,(T - t)$$

For any other assumed quantity of air per person take H_A in proportion.

Heat Required to Supply Radiation Losses. — Let

S = radiating surface, in square feet,
t = temperature, ° F., of outside air,
T = temperature, ° F., of inside air,
K = B.t.u. lost per hour per square foot of radiating surface per ° F. difference in temperature (*see table below*).

Then the heat lost due to radiation is

$$H_R = \Sigma\, KS\,(T - t),$$

where the summation includes all the radiating surfaces. Certain arbitrary additions are usually made to the value of H_R as thus calculated for the nature of the exposure, etc., see below.

The following values of K are taken from two papers, one by Wolff (*Jour. Frank. Inst., 1893*), the other by Hauss (*Trans. A.S.H.V.E., 1904*).

2-in. pine board....	0.28	....	Arches with air space.....	....	0.14

Allowances for Exposure, etc. — Hauss makes the following additions to the values of H_R as calculated from the above formula and constants:

	Per cent
Rooms with unusual exposure................	5
North, east, northeast, northwest and west exposures..............................	10
Ceiling between 13 and 15 ft. above floor.....	3⅓
Ceiling between 15 and 18 ft. above floor.....	6⅔
Ceiling over 18 ft. above floor................	10

For rooms heated daily, but where heating is interrupted at night, add

$$\frac{0.25\,(N-1)}{Z}\text{ per cent,}$$

where N = hours from cessation of heating to time of starting again, Z = hours from starting heating again until required room temperature is reached.

TOTAL HEAT REQUIRED. — If there are no sources of heat already in the room the total number of B.t.u. which must be supplied per hour by the heating device installed is

$$H = H_A + H_R,$$

where H_A and H_R have the values given above, H_R including the allowances for exposure, etc. If there are a number of people in the room, or a number of lamps, or electric machinery (as in a power house or substation) the additional B.t.u. required in excess of the heat given off by the people or apparatus is

$$H - H_M,$$

where H_M is the B.t.u. given out by the people and apparatus, and is calculated as follows:

Heat Given Out by Electric Machinery, Lamps and People. — A loss of 1 kilowatt for one hour in any piece of electric machinery or lamp corresponds to 3415 B.t.u. per hour. A person gives out about 400 B.t.u. per hour. Hence if L is the average number of kilowatts loss per hour due to all the lamps and electric machinery in the room and N the number of people in the room, then the total B.t.u. per hour supplied to the room by the machinery, lamps and people in it is

$$H_M = 3415\,L + 400\,N.$$

HEATING APPARATUS. — For dwellings, shops, etc., hot-air, hot-water or steam-heating systems are usually employed; for large buildings the last two only. In substations or power houses (e.g., a hydro-electric station) where the heat losses are not sufficient to provide enough heat, either steam or electric heaters are used.

J. K. Allen (*Trans. A.S.H.V.E.*, *1908*) gives the following values of K (= B.t.u. radiated per square foot per hour per ° F. difference in temperature between steam and outside air) for cast-iron radiators, from which the necessary square feet of radiating surface may be calculated when the number of B.t.u. required have been determined as outlined above.

VALUES OF K FOR CAST-IRON RADIATORS

Diff. in temp. bet. steam and air, ° F.	2-column radiator	3-column radiator	Diff. in temp. bet. steam and air, ° F.	2-column radiator	3-column radiator

M., *Elements of Heating and Ventilation*, Proc. Am. Soc. of Heat. and Vent. Eng., N. Y., 1896 to date.

[Wm. Kent.]

HEATING AND COOKING BY ELECTRICITY. — The essential element of an electric heating device is the "heating unit," which consists of a coil or plate of high-resistance wire or ribbon capable of supporting a high temperature (about 500° F. to 2200° F.) without deterioration. Data on a number of such resistor metals are given in the article on *Wires, Resistance*. When the heating unit is exposed directly to the air a non-oxidizing resistor must be used; nickel-chromium is a very satisfactory alloy for this purpose. German silver and nickel-steel alloys deteriorate rapidly at high temperatures when exposed to air.

Types of Heating Units. — A common form of heating unit used in flat-irons, chafing dishes, percolators, disc stoves, etc., is the encased disc, the resistor being either a ribbon wound on a mica disc or a grid stamped from a thin sheet of the alloy and mounted between thin sheets of mica; this type of unit is sometimes called a "monoplane heater." The radiant open-coil type of heating unit is used for toasters, grills, etc., mica or porcelain being used as the supporting insulator. Electric radiators for heating rooms are variously constructed, one type (G.E.) consisting of wire wound on asbestos tubes two inches in diameter and 22 inches long and covered with a coating of fire-proof cementing compound. When air is thus excluded German silver may be used as the resistor. A form of construction, called from its shape a "cartridge unit," is made of a high-resistance ribbon wound on a mica cylinder and coated with insulating cement; this unit is inserted in a hole in the casting which is to transfer the heat to the point where it is wanted. Cartridge units are used for disc stoves, grids and broilers. Where a comparatively low operating temperture is required, as in flexible heating pads, asbestos insulated wire woven into a sort of honeycombed mat is used.

Heating of Rooms. — The use of electric heaters for heating rooms is practically limited in this country to bathrooms, ticket booths, and intermittent auxiliary service in dwellings and offices. The power required to keep an ordinary sized room warm when the outside air is near the freezing point, ranges from about 1 to 2 watts per cubic foot; for more exact data see the article on *Heating of Buildings*. Were cost the only factor, electric heating, with electric energy at the present rates (2 to 10 cents per kilowatt-hour), would be out of the question. However, electric heating possesses the following advantages, which, in many instances, offset the higher cost, viz., (1) electric heaters may be fitted into places where coal or gas stoves could not be used, (2) the fire risk is less, (3) greater cleanliness is secured, and (4) the hygienic conditions are better.

Heating of Cars. — See article on *Railways, Energy Requirements for*.

Flatirons. — An internally-heated gas flatiron of household size burns about 5 cu. ft. of gas per hour. For continuous service with an externally-heated iron three irons are required, two heating while one is being used; for such service about 16 cu. ft. of gas are used per hour by the burner. An electric flatiron of household size takes about 550 watts. Hence, assuming gas to cost $1.00 per 1000 cu. ft. and electricity to cost 10 cents per kilowatt-hour, the energy cost per hour for each of the three types would be:

	Cents
Internally-heated gas flatiron	0.5
Externally-heated gas flatiron	1.6
Electric flatiron	5.5

However, the evident advantages of cleanliness, convenience, safety and comfort bring about a very extensive use of the electric flatiron, even though the the actual cost is greater than for coal or gas heating.

Electric Cooking. — Two types of electric "cookers" are in general use, the electric fireless cooker and the electric range.

Electric Fireless Cookers. — A number of designs of electric fireless cookers have been put on the market. An ingenious type is that made by the Berkeley Electric Cooker Co. This device consists of a food compartment, around which is wound a 550-watt heating element of nichrome ribbon, which in turn is surrounded by an air-tight water jacket partly filled with water and from which the air is exhausted, and this again is surrounded by a suitable thickness of heat-insulating material. Soon after the current is switched on, the water boils and the pressure produced in the water jacket forces out a metal diaphragm, which opens the main switch when the temperature of the water reaches about 212° F.; when the temperature falls below this value, the diaphragm automatically closes the switch again. Actual tests have shown that the temperature may thus be kept practically constant and that the current is on only about one-fifth of the time. Such a device takes care of that cooking which is the most expensive, viz., boiling, stewing and steaming.

Electric Ranges. — There are several types of electric ranges on the market designed to do all the cooking for from two persons up to two hundred. In one type (Simplex) "hot plates" in the top of the range are used, over which fit special flat-bottomed utensils with an apron or flange around the rim; good contact between the utensil and plate is secured by a lock or clamp with wedging action. In another type (G.E.) the cooking utensil is set into a chamber in the top of the range and covered up by an ordinary stove lid. The ovens are built of light sheet steel and have double walls, the space between being filled with a non-conductor of heat. Pilot lights are used to indicate when the current is on or off.

Advantages of Electric Cooking. — The following advantages of electric cooking over coal or gas are claimed: (1) cleanliness, (2) safety, (3) convenience, (4) a cool kitchen, (5) better cooking, especially broiled meats, (6) less shrinkage of meats, (7) no odors, (8) exact reproducibility of conditions, (9) actual saving in cost under certain conditions.

Cost of Electric Cooking. — A great amount of data on the kilowatt-hour consumption and cost per meal has appeared of late in the various technical journals. The average consumption per person per meal ranges from about 0.2 to 0.8 kw-hr., which at 3 cents per kilowatt-hour corresponds to a cost per person per meal of from 0.6 to 2.4 cent. The actual cost in any particular case of course depends upon the number of persons served, the food cooked and the kilowatt-hour cost.

[A. P. KITCHEN.]

HOISTS, ELECTRIC. — (*See also Cranes; Elevators; Motors, Industrial Applications of; Telpherage.*) A hoist is a machine for raising and lowering weights. The most common application is in mines, to which service the following article is devoted.

The hoists most generally used are of the drum type, the drums being either cylindrical or conical or a combination of the two. As a rule two drums operating in balance are used for each hoist. The weight of the skip, or cage and car carrying the ore, is balanced by a similar empty skip which is lowered in a second compartment simultaneously with the hoisting of the loaded skip in the first, the loaded skip being dumped at the top and the empty one loaded at the bottom, and the cycle being repeated. The difference between balanced and unbalanced hoisting is that the static load when working unbalanced is greater than when working balanced, and the change of load due to the rope is only half as great.

Preliminary Data. — In dealing with hoisting problems the following data are required:

Present and ultimate depth of shaft.
If inclined, give angle of inclination with horizontal, or grade, in per cent.
Weight of material per trip.
Weight of skip or cage and car.
Diameter and weight of rope.
Size of tail rope, if used.
Rope speed.
Number of trips per hour.
Time required for loading and unloading.
Double or single drum.
Diameter and weight of drums.
Motor geared or direct connected.
Hoist balanced or unbalanced.
If balanced, will unbalanced operation ever be necessary?

Besides the above, the ordinary data of the power supply system must be known; also the restrictions as to permissible peak loads, so as to make it possible to decide whether a load equalizing set will be required.

For cylindrical hoists the power required for the various periods of the duty cycle can be figured directly in horse-power. For conical drums the problem is somewhat more complicated and a moment diagram is usually first figured and plotted, and then converted into horse-power.

HOIST FORMULAS FOR CYLINDRICAL DRUMS. — Let

w = weight of ore in pounds,
w_r = weight of one rope in pounds,
w_a = weight of rope wound on drum during acceleration period,
w_d = weight of rope wound on drum during retardation period,
w_s = weight of one skip or cage and car,
W = weight of revolving parts* (except motor armature) $+ w + 2w_r + 2w_s$ (balanced operation),
W' = weight of revolving parts $+ w + w_r + w_s$ (unbalanced hoisting),
W'' = weight of revolving parts $+ w_r + w_s$ (unbalanced lowering),
V = maximum rope speed in feet per second,
t_1 = period of acceleration in seconds,
t_2 = period of full-speed running in seconds,

* The weight of the motor armature should not be included in the weight of revolving parts W, as the horse-power obtained from the formulas is the output and not the input.

t_3 = period of retardation in seconds,
t_0 = period of rest in seconds,
T = actual hoisting time in seconds (not including rest),
L = depth of shaft in feet (total travel of rope),
θ = angle of incline with horizontal,

$$w_a = \left(\frac{V}{2}t_1\right) \times \text{(weight of rope in pounds per foot)},$$

$$w_d = \left(\frac{V}{2}t_3\right) \times \text{(weight of rope in pounds per foot)},$$

$$t_{eqv.} = \frac{L}{V}$$

$$t_1 + t_3 = 2\,(t_{eqv.} - t_2)$$

$$t_2 = \frac{2\,t_{eqv.} - (t_1 + t_3)}{2},$$

$$V = \frac{L}{T - \frac{t_1 + t_3}{2}},$$

$$t_1 + t_3 = 2\left(T - \frac{L}{V}\right).$$

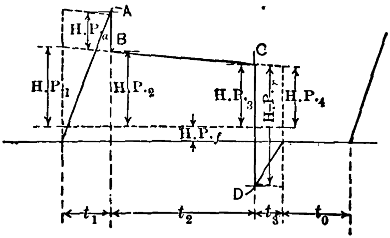

Fig. 1. Duty Cycle Diagram

The power required for each portion of a typical duty cycle, a diagram of which is given in Fig. 1, is indicated in the accompanying table.

Horse-power output at point $A = (HP)_a + (HP)_f + \left[\frac{(HP)_1 + (HP)_2}{2}.\right]$

Horse-power output at point $B = (HP)_2 + (HP)_f$.

Horse-power output at point $C = (HP)_3 + (HP)_f$.

Horse-power output at point $D = (HP)_r + (HP)_f + \left[\frac{(HP)_3 + (HP)_4}{2}.\right]$

$(HP)_r$ is always negative. If D is negative, power must be absorbed by either the motor or the brakes during the period of retardation. If D is positive, power must be delivered by the motor during retardation.

Motor Rating. — The rating of the motor can be obtained from the following formulas:

For Alternating Current.

$$(HP) = \sqrt{\frac{A^2 t_1 + \frac{B^2 + C^2 + BC}{3} \times t_2 + D^2 t_3}{0.50\,t_1 + t_2 + 0.50\,t_3 + 0.25\,t_0}}.$$

If D is negative the factor $(D^2 \times t_3)$ should be eliminated from the equation.

For Direct Current.

$$(HP) = \sqrt{\frac{A^2 t_1 + \frac{B^2 + C^2 + BC}{3} \times t_2 + D^2 t_3}{0.75\,t_1 + t_2 + 0.75\,t_3 + 0.5\,t_0}}.$$

SYSTEMS OF ELECTRIC HOISTING. — Of the large number of systems of electric hoisting which have been proposed, by far the greater majority can be included in the three following systems:

1. Those driven by induction motors.

HORSE-POWER FOR DUTY CYCLE

Period	Symbol (see Fig. 1)	Balanced hoisting	Unbalanced Hoisting: Hoisting	Unbalanced Hoisting: Lowering
Acceleration (max. value)	$(HP)_a$	$+\frac{WV^2}{32.2\times 550\,t_1}$	$+\frac{W'V^2}{32.2\times 550\,t_1}$	$+\frac{W''V^2}{32.2\times 550\,t_1}$
Retardation (max. value)	$(HP)_r$	$-\frac{WV^2}{32.2\times 550\,t_3}$	$-\frac{W'V^2}{32.2\times 550\,t_3}$	$-\frac{W''V^2}{32.2\times 550\,t_3}$
Hoisting (eqv.) at beginning of acceleration	$(HP)_1$	$+\frac{(w+w_r)\,V\sin\theta}{550}$	$+\frac{(w+w_r+w_s)\,V\sin\theta}{550}$	$-\frac{w_s\,V\sin\theta}{550}$
Hoisting, full speed at end of acceleration	$(HP)_2$	$+\frac{(w+w_r-2w_a)\,V\sin\theta}{550}$	$+\frac{(w+w_r+w_s-w_a)\,V\sin\theta}{550}$	$-\frac{(w_s+w_a)\,V\sin\theta}{550}$
Hoisting, full speed at end of full-speed run	$(HP)_3$	$+\frac{(w-w_r+2w_d)\,V\sin\theta}{550}$	$+\frac{(w+w_s+w_d)\,V\sin\theta}{550}$	$-\frac{(w_s+w_r-w_d)\,V\sin\theta}{550}$
Hoisting (eqv.) at end of retardation	$(HP)_4$	$+\frac{(w-w_r)\,V\sin\theta}{550}$	$+\frac{(w+w_s)\,V\sin\theta}{550}$	$-\frac{(w_s+w_r)\,V\sin\theta}{550}$
H.P. friction	$(HP)_f$	$+[(HP)_{f1}+(HP)_{f2}+(HP)_{f3}]$	$+[(HP)_{f1}+(HP)_{f2}+(HP)_{f3}]$	$+[(HP)_{f1}+(HP)_{f2}+(HP)_{f3}]$
H.P. mechanism friction (including head sheave)	$(HP)_{f1}$	$\frac{\frac{(HP)_1+(HP)_4}{2}}{\text{Eff.*}}-\frac{(HP)_1+(HP)_4}{2}$	Approximately equal to 60%-75% of $(HP)_{f1}$ for balanced hoisting.	Approximately equal to 60%-75% of $(HP)_{f1}$ for balanced hoisting.
Skip or car friction (slope only) (Coefficient of friction = 0.02)	$(HP)_{f2}$	$\frac{0.02\,(w+2w_s)\,V\cos\theta}{550}$	$\frac{0.02\,(w+w_s)\,V\cos\theta}{550}$	$\frac{0.02\,w_s\,V\cos\theta}{550}$
Rope (slope only) (Coefficient of friction = 0.10)	$(HP)_{f3}$	$\frac{0.10\,w_r\,V\cos\theta}{550}$	$\frac{0.10\,w_r\,V\cos\theta}{550}$	$\frac{0.10\,w_r\,V\cos\theta}{550}$

Efficiency for direct connection 0.88
Efficiency for single-gear reduction 0.85
Efficiency for double-gear reduction 0.80

2. Those driven by direct-current motors, power for which is supplied by a motor-generator set.
3. Those driven by direct-current motors, power for which is supplied by a flywheel motor-generator set.

1. Induction-motor System. — In the first and simplest system the speed of the direct-connected induction motor is controlled by a variable resistance, usually a variable resistance in the rotor circuit, which resistance is usually some sort of a water rheostat. The advantages of this system are: simplicity, low first cost, high motor efficiency when the hoist is running at full speed (approximately 90 per cent), no power consumed when the hoist is at rest. The disadvantages are: low motor efficiency during acceleration (approximately 45 per cent), no power is returned to supply system during retardation, large power consumption for small movements of cage, fluctuation of power demand.

2. Direct-current Motor System. — In the second system the hoist is driven by a separately excited direct-current motor, receiving power from the alternating-current supply system through a synchronous or induction motor-generator set. The hoist motor is controlled by varying the voltage of the generator, which is separately excited, one generator being used for each motor. The advantages of the system are: high motor efficiency during acceleration (approximately 80 per cent), return of large portion of energy during retardation. The disadvantages are: low motor efficiency when running at full speed (approximately 82 per cent), loss in motor-generator set when hoist is at rest, high initial and operating expense, fluctuation of power demand.

3. Direct-current System with Flywheel. — The third system takes advantage of the low first cost and efficiency of the flywheel (*see Flywheels for Load Equalization*) as a means for storing and returning large quantities of power for short intervals. This system is similar to the second, except for the addition of a flywheel to the induction-motor-generator set, and an automatic regulator for varying its speed. In its most common form this regulator consists of a water rheostat connected in series with the induction-motor armature. The resistance is varied by means of movable electrodes suspended from an arm mounted on the shaft of a small induction motor, which is connected in series either directly or through series transformers, with the induction motor of the flywheel set. The regulator motor is so connected that its torque opposes the weight of the electrodes, which are partially counterbalanced to reduce the size of the *regulator* motor to a minimum, and to permit of an adjustment of the regulator for different values of line current. When the line current exceeds the value for which the regulator is adjusted, the torque of the motor overbalances the weight of the electrodes, lifting them and inserting resistance in the armature circuit of the induction motor. This causes it to slow down, and allows the flywheel to assist in driving the generator during the peak loads.

Steam vs. Electric Systems. — A comparison between a steam system and these three electrical systems is given in the following table, in which the fuel and ore ratios for each are given for a small installation hoisting from a 2000-foot level, and a large installation hoisting from a 6000-foot level.

In addition to the saving in fuel which may be realized by the use of electric hoists instead of steam hoists, there is a very material reduction in the labor, the cost of which is chargeable against the hoist. This may amount to the wages of one or two men in the boiler house if power is developed by the mining company, or of the whole boiler house force if power is purchased, and frequently the wages of one man in the hoist house.

Power Consumption. — So many factors enter into the cost of electric hoisting that each individual case must be analyzed separately. An approximate

Installation	Hoisting system	Coal burned, tons per day	Ore hoisted, tons per day	Ratio tons ore to tons coal
Small, hoisting from 2000-foot level.	Steam	47	1780	40
	Electric, first system	13	1780	137
	Electric, second system	15	1780	119
	Electric, third system	16	1780	110
Large, hoisting from 6000-foot level.	Steam	65.5	1580	24
	Electric, first system	23	1580	69
	Electric, second system	24	1580	66
	Electric, third system	25	1580	63

estimate of the power consumption would be from 1¼ to 2¼ kilowatt-hours per 1000 ton-feet, the tonnage, in the case of unbalanced hoisting, including the weight of the ore and skip, while for balanced hoisting only the ore.

SPECIFICATIONS FOR ELECTRIC HOIST.* — The following memoranda are intended to assist in writing specifications. See also article on *Elevators, Electric* and the article on *Specifications*.

Principal Characteristics and Conditions of Service. — General description and use of hoist. Motor voltage and frequency (*see articles on Motors*). Mechanical rating, i.e., load to be lifted a specified height in a specified time. Proportion of time above load will be carried and of time machine is at rest.

Details of Construction. — Length of hoisting rope and whether or not rope is to be supplied. If so, details of rope and of hook or other device. Brake requirements. Lubrication details. Materials of principal parts.

Performance and Tests. — Maximum load to be lifted. Maximum speed descending. How tests are to be conducted.

HYDRAULICS. — (*See also Dams; Hydrology; Pipes and Piping; Power Stations, Hydro-Electric; Water Wheels; Water Wheels, Speed Regulation of.*) Hydraulics comprises the principles and laws governing the motion and mechanical reactions of liquid bodies. There are two general divisions of the subject: Hydrostatics, which refers to liquids at rest; and Hydrodynamics, which refers to liquids in motion. This article will be confined to that portion of the subject which relates more directly to the problems met with in the study of water-powers.

Head and Pressure. — In water power terminology the word *head* means the difference in level of water between two points. It is usually expressed in feet. The pressure of water in a pipe, for instance, is usually given as so many feet head and not as so many pounds per square inch. The relation between head in feet, h, and pressure in pounds per square inch, p, is as follows:

$$h = 2.31\,p,$$
$$p = 0.433\,h.$$

These formulas assume 62.4 lb. as the weight of 1 cu. ft. of water. See also *Units and Conversion Factors.*

POWER OF WATER. — Water exerts its power by falling through some distance and its action is exactly analogous to that of a falling weight. The total number of foot-pounds of work per second which a stream is capable of performing is equal to the weight of a cubic foot of water, multiplied by the number of cubic feet flowing per second, and by the head or difference in level of the stream at the two places under consideration. If the horse-power is desired, divide the number of foot-pounds of work done per second by 550. This gives the "theoretical" horse-power, i.e., it includes not only the power available for useful work but also the power lost in friction in the various water passages, in the wheel, and in giving velocity to the water discharged from the wheel.

Let Q = number of cubic feet of water flowing per second;
h = total head or difference in elevation between pond and tail water;
ϵ = over-all efficiency, as a decimal, including all losses up to wheel shaft.

Then the net power available at the wheel shaft is

$$P = 0.114\,Qh\epsilon \qquad \text{horse-power.}$$

The over-all efficiency (pond to wheel shaft) in a well-designed water-power station should not vary greatly from 80 per cent. This does not include the losses in electric machinery nor the losses in long pipe lines.

Friction and Velocity Head. — Neglecting any leakage of water (i.e., assuming no water to pass into the tail race except through the wheel) the losses of energy due to friction and to giving velocity to the water may each be represented by a loss of head. The total loss of head due to friction is called the "friction head," and may be represented by the symbol h_f; the loss of head due to giving velocity to the water is called the "velocity head," and may be represented by the symbol h_v. The net useful head is the $h_u = h - (h_f + h_v)$, where h is the total head, and the efficiency is

$$\epsilon = 1 - \frac{h_f + h_v}{h}.$$

The friction head depends upon the cross section, shape and roughness of the water passages, see below, and in the case of a water wheel the loss due to the friction in the bearings may also be considered as contributing to the friction head. The friction head which can be economically allowed in the intake and discharge passages depends so greatly upon local conditions that no general rules can be given here.

The net velocity head may be expressed as

$$h_v = \frac{v^2}{2g},$$

where v is the linear velocity, in feet per second, of the tail water where it comes out at atmospheric pressure, and g is the gravitational acceleration (32.16 feet per second per second). The importance of a low discharge velocity is therefore apparent.

FLOW THROUGH PIPES. — See articles on *Pipes and Piping* and *Water Wheels, Speed Regulation.*

FLOW THROUGH OPEN CHANNELS. — The term channel includes all forms of closed conduits when flowing partly full as well as ordinary stream beds or canals. The rate of flow in such a case depends upon the slope given to the water surface. It is difficult to treat analytically the flow in natural channels, because of the wide divergence in shape of cross-section and nature of sides and bottom of channel. Only artificial channels are considered here, although the same formulas apply to any section of natural channel which has the same cross-section throughout.

Chezy's Formula. — This formula gives the relation between the linear velocity of the water, hydraulic radius and the slope and a coefficient which must be determined experimentally, viz.,

$$v = C\sqrt{rs},$$

where v = linear velocity of water in feet per second, r = hydraulic radius in feet, s = slope of stream (i.e., the difference in elevation between two points in the water surface divided by the slope distance between the two points measured along the surface) and C is an experimentally determined coefficient which may also be expressed by the empirical formulas given below. These formulas, however, may give results from 5 to 10 per cent in error.

The values of C which may be expected in ordinary cases are as follows:

	Values of C
Very smooth cement or timber	125 to 150
Ordinary timber, concrete, brickwork, etc	100 " 130
Rough masonry or firm gravel	70 " 90
Earth bed in good condition	50 " 75
Earth bed in bad condition	25 " 50

Hydraulic Radius. — This term is used to designate the quotient of the area of a cross-section, e.g., $ABCD$ in Fig. 1, by the *wetted* perimeter of the channel walls and bottom, $AB + BC + CD$ in Fig. 1.

Fig. 1.

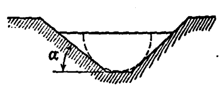

Fig. 2.

Best Section to Use. — The most advantageous cross-section to use is that having the maximum value of the hydraulic radius r. The semi-circle is therefore the best but is the most difficult to construct and to maintain. Of trapezoidal cross-sections the half hexagon is the best and of rectangular cross-sections the half square. In unlined earth channels the trapezoidal cross-section must be used. Of these sections the best to use is shown in Fig. 2. The angle α is determined from the character of the soil. The sides and bottom are made tangent to a semi-circle having its center at the water surface.

Kutter's Formula. — This is one of two formulas in common use for expressing the coefficient C in Chezy's formula in terms of the dimensions of the cross-section of the channel. Kutter's formula (published in 1869) is

$$C = \frac{41.65 + \frac{0.00281}{s} + \frac{1.811}{n}}{1 + \left(41.65 + \frac{0.00281}{s}\right)\frac{n}{\sqrt{r}}},$$

where r and s are as above, and n is the "coefficient of roughness," values of which for various channel linings are as follows:

	Values of n
Planed timber, glazed or enameled surfaces	0.009
Smooth clean cement	0.010
Unplaned timber, new well-laid brickwork	0.012
Smooth stonework, ordinary brickwork, iron	0.013
Rough ashlar and good rubble masonry	0.017
Firm gravel	0.020
Earth in ordinary condition	0.025
Earth with stones, weeds, etc	0.030
Earth or gravel in bad condition strewn with detritus	0.035

Bazin's Formula. — The second formula commonly used for expressing the coefficient C in Chezy's formula is that given by Bazin in 1897, viz.,

$$C = \frac{87}{0.552 + \frac{m}{\sqrt{r}}},$$

where r is as above and m is a "coefficient of roughness" values of which are as follows:

	Values of m
Very smooth cement surfaces or planed boards	0.06
Concrete, well-laid brick, unplaned boards	0.16
Ashlar, good rubble masonry, poor brickwork	0.46
Earth beds in perfect condition	0.85
Earth beds in fair or ordinary condition	1.30
Earth beds in bad condition covered with debris	1.75

Bazin's formula is probably the best, and it certainly is the simpler one to use. Many engineers, however, prefer to use Kutter's formula, which has been graphically solved in a book of diagrams by Prof. Church (Wiley & Sons).

FLOW OVER WEIRS.—In hydraulics the term "weir" is used in general to designate any kind of a dam across a stream, and in particular to designate a vertical notch, usually rectangular, by means of which the quantity of water passing a given point may be determined, Fig. 3.

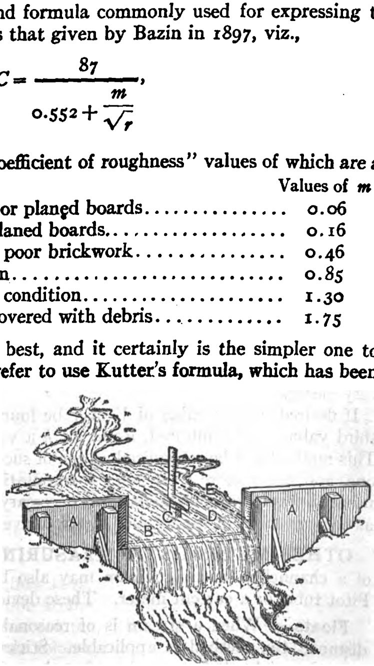

Fig. 3.

Definitions Regarding Weirs. —The "crest" is the horizontal edge of the weir. The "head" on a weir is not the depth of water over the crest, but is the difference in level between the crest and the reservoir surface.

A "fully contracted" weir is one in which each end of the weir is at a distance of at least 3 times the head from the sides of the channel. A "suppressed" weir is one in which the sides of the channel form the end of the weir. The "velocity of approach" is the velocity of the water in the channel leading to the weir. For a given head on the weir the quantity of water passing the weir depends somewhat upon the velocity of approach.

Weir Formulas. — The formulas below are applicable only when the following conditions are fulfilled: (1) edges of weir sharp, smooth and beveled on the down stream side as shown in Fig. 3 (or a thin metal plate bolted to a wooden board may be used for the edge of the weir), (2) the crest of the weir must be at least 3 times the head above the bottom of channel, (3) the crest of the weir must have a length at least 3 times the head on it. In all the formulas

Q = cu. ft. of water per sec. flowing over weir,
H = measured head on weir, in ft.,
h = head in ft., due to velocity of approach,
H_1 = "effective" head on weir, in ft.,
b = breadth of weir (length of crest) in ft.

Then for a *fully contracted* weir

$$Q = 3.33\,(b - 0.2\,H)\,H_1^{\frac{3}{2}}$$

and for a *suppressed* weir

$$Q = 3.33\,bH_1^{\frac{3}{2}},$$

when the cross-section of the stream immediately above the weir is more than $6\,bH$ the effect of the velocity of approach is negligible and H_1 may be taken equal to H. When the cross-section of the stream is less than $6\,bH$, then

$$H_1^{\frac{3}{2}} = (H + h)^{\frac{3}{2}} - h^{\frac{3}{2}}.$$

It should be carefully noted that the above formulas hold only under the conditions specified; when applied to weirs of other shape (e.g., a dam with a flat or curved surface) a coefficient other than 3.33 must be used (*see Dams*).

Determination of Velocity Head (h). — First take $H_1 = H$, and from the above formula calculate Q. This value of Q divided by the cross-section A of the channel immediately above the weir gives an approximate value for the velocity of approach V. The head due to the velocity of approach is then approximately $h = \dfrac{V^2}{64.32}$. Recompute the discharge Q, calculating $H_1^{\frac{3}{2}}$ from the measured head H and this value of h. This will usually give the discharge very closely.

If desired, a new value of V may be found from this new value of Q and a third value of Q computed, using for h a value based on the new value of V. This method will be recognized as one of successive approximations. Generally one, and never more than two, recomputations are all that are necessary. In using the weir formulas given it is necessary to adhere to this method strictly, as the constants in the formulas were derived by using this method.

OTHER METHODS OF MEASURING FLOW. — The rate of discharge of a channel or natural stream may also be measured by means of floats, a Pitot tube, or a current meter. These devices are briefly described below.

Floats. — When a stream is of reasonably regular cross-section for a little distance, this method is applicable. Sticks about 1¼ inches in diameter, sufficiently weighted at one end so that they will float upright in the water, should be used. Surface floats are unreliable because of the influence of wind, skin friction of the water, etc. The floats are started at the beginning of a measured course and the time which they take to reach the end of the course is accu-

rately taken. The velocity of the stream is thus obtained; this multiplied by the area of the cross-section gives the rate of discharge.

The floats should be started from various points in the width of the stream in order to obtain the average velocity as nearly as possible. They should be long enough to come as close as practicable to the bottom of the stream without touching, in order to average the velocities, which are variable throughout the depth of the stream. This method is less accurate than the use of the current meter.

Current Meters. — The ordinary current meter is essentially a wheel revolved by the water and held with its axis perpendicular to the direction of flow by means of vanes. Some means of recording the revolutions are provided. The meter must be rated by drawing it through still water at various measured speeds. Elaborate apparatus for meter rating is maintained by the Government and by various universities. Measurements of the velocity of the stream are made at frequent intervals across the stream and at varying depths, and the average velocity determined; this multiplied by the cross-sectional area of the stream for the height of water existing at the time gives the rate of discharge.

Pitot Tube. — This is merely an open tube having a right-angle bend, the tube is placed in the stream in the position shown in Fig. 4, the lower end being directed against the current. The height h to which the water rises in the tube above the surface of the stream is equal to the velocity head, or the linear velocity of the stream is

$$v = \sqrt{2gh},$$

where h is in ft., $g = 32.16$ ft. per sec. per sec., and v in ft. per sec. This formula does not apply to the flow through a pipe, since the pressure head must also be taken into account. For measuring the flow in pipes a differential gage of this type may be used, but the Venturi meter (see below) is better suited to such measurements.

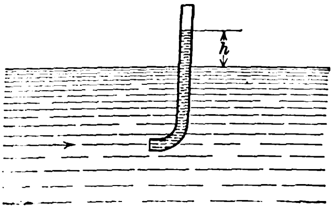

Fig. 4. Pitot Tube

Venturi Meter. — This meter, Fig. 5, serves as a simple and accurate means of measuring the discharge through a pipe. The meter consists essentially of an hour-glass-shaped section of pipe, with smoothly rounded internal walls, into which are fitted two gages as shown. The planes of the internal openings of gage pipes are at right angles to the direction of the current. Referring to Fig. 5, let

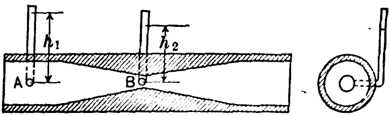

Fig. 5. Venturi Meter

a_1 = area, in sq. ft., of the cross-section at A,
a_2 = area in sq. ft., of the cross-section at B,
h_1 = reading of gage at A, ft. of water column,
h_2 = reading of gage at B, ft. of water column,
g = acceleration due to gravity, ft. per sec. per sec.,
C = a coefficient, ranging from 0.94 to 1.00, which takes into account the friction in the meter.

Then the discharge through the pipe in cu. ft. per sec. is

$$Q = C \frac{a_1 a_2}{\sqrt{a_1^2 - a_2^2}} \sqrt{2 g (h_1 - h_2)}.$$

Ordinary pressure gages may be used at A and B, and their reading converted to feet of head, with a correction added for height of gage above center line of meter.

FLOW THROUGH NOZZLES. — Nozzles for practical purposes are made either of a conical shape with a cylindrical tip of sufficient length so that the water will touch it, or are bell-shaped with the sides parallel at the point of exit. The discharge through such nozzles in cubic feet per second is found by multiplying the product of the area of the nozzle in square feet and its "coefficient of discharge" by $\sqrt{64.32\,H}$, where H is the sum of the pressure head and velocity head at the base of the nozzle, in feet. The value of the coefficient of discharge for nozzles averages about 0.97.

When the nozzle is used for the purpose of measuring water a pressure gage is usually attached to the base of the nozzle. This gage should be at the same height as the base of the nozzle. If from necessity it is located at a higher point, the difference in elevation between the center of the gage and the center of the nozzle base must be added to the gage reading. If it is below, the difference in elevation must be subtracted. This gage measures only the pressure head at its point of attachment. There is also at this point a considerable velocity in the pipe which adds materially to the discharge. Instead of using the total head H, the discharge in cubic feet per second may be expressed in terms of the pressure head only by the formula

$$Q = a \sqrt{\frac{2 gh}{\left(\frac{1}{C}\right)^2 - \left(\frac{a}{A}\right)^2}},$$

where h = pressure head in feet at base of nozzle (from gage), a = cross-sectional area of nozzle tip in square feet, A = cross-sectional area of pipe in square feet at point of attachment of gage, C = coefficient of nozzle, g = gravitational acceleration in feet per second per second. When $C = 0.97$ and $g = 32.16$,

$$Q = 8.02\, a \sqrt{\frac{h}{1.063 - \left(\frac{a}{A}\right)^2}}.$$

BIBLIOGRAPHY. — A complete bibliography up to 1908 is given in Mead's *Water Power Engineering*. Among the references there given may be noted Merriman, M., *Treatise on Hydraulics*, N. Y., 1903; Bellasis, E. D., *Hydraulics with Tables*, N. Y., 1911. Some more recent references are Russell, G. E., *Text Book on Hydraulics*, N. Y., 1912; Hughes and Safford, *A Treatise on Hydraulics*, N. Y., 1911.

[L. E. MOORE.]

HYDROLOGY. — (*See also Hydraulics; Power Stations, Hydro-Electric.*) In the broadest sense, hydrology is the science of water, including its properties, the phenomena and natural laws associated with it, its distribution over the earth's surface, and in fact everything relating to water as a physical entity. As ordinarily employed, however, the term is limited to include only those laws and properties which have to do directly with its distribution over the earth's surface, particularly the relations between rain-fall, natural drainage, and the flow of water in rivers.

Hydrological Data Required in Water-power Engineering. — To determine whether a particular stream is capable of development and the economical extent of its possible development, it is necessary to know not only the *average* rate of flow of the water in the stream, but also the *variation* in flow from day to day and from year to year. In those rare cases where gaging stations have been maintained for a number of years on a stream these data may be directly determined. In most cases, however, it is necessary to estimate the flow from the rain-fall over the water shed drained by the stream. An estimate of this kind requires careful judgment, because the intensity and distribution of the rain-fall have a very important influence. The character of the drainage area, whether sandy, rocky, or clayey, the character of the topography and the character and extent of the vegetation are all important. While it is difficult to reduce these different elements to a mathematical formula, the general principles involved are discussed below.

RAIN-FALL. — Rain-fall is usually expressed in inches, the number of inches being the depth of rain water which would be caught in a vessel with vertical sides set out in the open. The records of rain-fall may be obtained from the United States Weather Bureau in Washington, D.C. Records covering as extended a period and as wide a portion of the watershed under consideration as is practicable should be obtained. Too absolute dependence should not be placed on these results, as the intensity of rain-fall at different places in the drainage area of the stream under consideration may be quite variable, not only in general, but also in particular storms. It is conceivable that a station for recording rain-fall might be located at a point in an area where the annual precipitation is far above or below the average, although such a condition is not likely to occur.

The average rain-fall for an average year over an area, multiplied by the area, will give the total average rain-fall. For power purposes it is important to know whether this average is fairly representative, or whether some years may fall far below the average. If the latter be the case it may be financially practicable to develop only on the basis of minimum rain-fall, if at all. Where records for an area do not exist, it may be possible to obtain records for an area at a similar altitude for a similar locality. These records may be used for an estimate, but such an estimate should not be relied upon too implicitly.

RUN-OFF. — By the "run-off" from any area is meant the amount of rain water falling on this area which ultimately finds its way into the stream or streams draining this area. Run-off may be expressed either in inches or in per cent of the rain-fall on the given area.

Factors Affecting Run-Off. — The primary factor is of course the rain-fall. For a given rain-fall, the nature of the soil, topography, climate and vegetation all affect the run-off. A porous, sandy soil may absorb nearly all the rain-fall, whereas a rocky one will absorb little or none. The run-off from steep slopes is much more rapid than from gentle ones. The climate has a considerable effect. In this connection the effect of temperature conditions should be noted. Rain, falling on frozen ground, runs off almost at once. Trees and

vegetation absorb more or less moisture and their roots obstruct the flow of ground-water to an extent which governs very largely the rapidity with which the water reaches the stream. Forests on a water-shed are the best means of equalizing stream flow throughout the seasons and preventing floods. The shade which forests cast has an extremely important effect on evaporation, reducing it very considerably, and consequently making available a much larger proportion of the rain-fall for power purposes. Fig. 1 shows the probable extreme variations in the relation between rain-fall and run-off (*from Proc. Eng. Club, of Phila., 1895*).

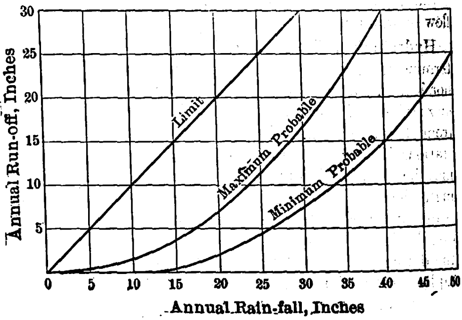

Fig. 1.

Formula for Run-Off in Terms of Rain-Fall. — J. D. Justin (*Proc. A.S.C.E., Vol. 39, p. 1211*) gives the following formula for the *annual* run-off, which applied to a number of drainage areas in the Eastern States gave results which checked with the actual run-off to within 10 per cent. It should be applied with caution to other parts of the country as both the coefficient 0.934 and the exponent 0.155 may vary under other climatic conditions. It should be applied to give the annual, not the monthly, run-off. Let C = annual run-off, in inches, on the watershed, R = annual rain-fall, in inches, on the watershed, S = "slope" of the watershed, defined as the difference in elevation in feet between highest and lowest point divided by the square-root of the area in square feet, T = mean annual temperature on watershed, in degrees Fahrenheit (*see next paragraph*); then

$$C = \frac{0.934\, S^{0.155} R^2}{T}.$$

Determination of Mean Annual Temperature (T). — Mean annual temperature can be obtained from the *Summary of Climatological Data for U.S. by Sections* issued by the U.S. Weather Bureau. If the watershed is mountainous and the observations of temperature are taken only in the valleys, the mean annual temperature over the whole watershed will be lower than that at the stations. To obtain the actual mean temperature (item 6 below) over the entire watershed from the observations at the stations, proceed as follows: (1) Take the average temperature at the stations; (2) Take the average elevation for the same stations; (3) Find the "average" elevation of watershed, i.e., the sum of the elevations above sea level of the highest and lowest points divided by 2; (4) Take the difference between the average elevation of the stations and the average elevation of the watershed; (5) Find the mean difference in temperature per foot of increase in elevation, by comparing records and elevations at the several stations; (6) Multiply (4) by (5) and subtract the result from (1).

STREAM FLOW. — The most satisfactory way of determining the water available from a given stream is to make a direct measurement of the rate of discharge. When the stream is small the number of cubic feet per second may be readily and cheaply measured by constructing a weir across it; see article on *Hydraulics*. When the stream is large it is necessary to measure the linear

velocity of the water at various points in a given cross-section, using for this purpose some form of current meter, or Pitot tube, or floats; see *Hydraulics*. From these velocity measurements at various intervals across the stream and at various depths, the average linear velocity of the water is determined; this, in ft. per sec., multiplied by the cross-section of the stream in sq. ft. gives the number of cu. ft. per second (frequently called "second-feet") flowing.

Rating Curve. — To obtain daily records of the stream flow at the chosen section a permanent post (called a gage), usually graduated in feet and inches, may be set up, and the height of water noted corresponding to the discharge under various stream conditions. A curve, called a "rating curve," see Fig. 2, may then be plotted, giving the discharge in cu. ft. per sec. as abscissa and the gage height as ordinate. Such a curve will in general be irregular due to the irregular shape of the cross-section of the stream for various depths of water. After a sufficient number of velocity measurements for various gage heights have been taken to give the shape of the rating curve, it is only necessary to make daily observations of the gage height in order to obtain a daily record of the stream flow.

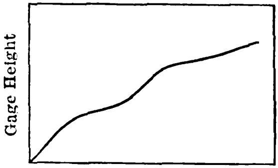

Fig. 2.

U.S. Government Records of Stream Flow.— The U.S. Government has maintained for a number of years gaging stations at one or more points on the larger rivers and their important tributaries. These records are published in the Annual Reports of the U.S. Geological Survey (1888 to 1900) and in the Water Supply and Irrigation Papers (1896 to date) also issued by the U.S. Geological Survey. Even though there are no government records for the particular stream under consideration, the records for a neighboring stream will be found of value in arriving at the probable relation between run-off and rain-fall for the stream in question. If the power project be a large one, it may be desirable to establish a gaging station and maintain it for at least one year.

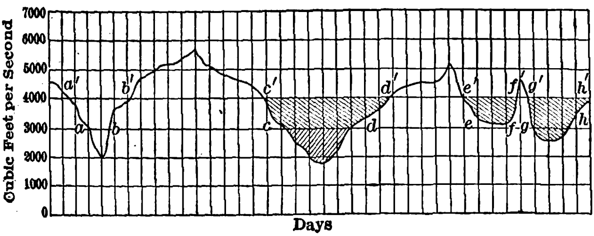

Fig. 3.

Hydrograph. — The hydrograph is a curve showing rate of flow of water as ordinates and time as abscissas; see Fig. 3. The quantities may be expressed in any units, but usually the rate of flow is expressed in cubic feet per second and the time in days. The average flow in cubic feet per second is plotted on the day during which the flow occurred. This is done for each successive day. A curve drawn through the points so obtained is the hydrograph. It must be clearly understood that the word day refers to some definite date, as Oct. 3, 1913, and not day in the abstract.

It should be noted that the hydrograph for different stations along the course of a stream will in general differ not only in the heights of the ordinates (average

rate of flow) but will also differ in shape, due to the difference in run-off from the different portions of the watershed.

Mass Curve. — The mass curve is a graphical representation of the total available amount of water during any period. Abscissas represent time and ordinates total net quantity available up to the date represented by the abscissa allowing for evaporation, seepage, etc. The time scale is usually months, while the water scale may be (1) inches on the drainage area, (2) total cubic feet, (3) acre-feet, or (4) second-feet-months (i.e., an average flow of Q cu. ft. per sec. for M months is MQ second-feet-months). The slope of the curve at any point indicates the rate of flow at that time.

STORAGE AND PONDAGE. — In water-power engineering the term "storage" is used when referring to a reservoir of sufficient capacity to equalize the flow of a stream from month to month, and the term "pondage" is used when referring to a reservoir (usually the pond above the dam at the power-house site) of a capacity only sufficient to equalize the flow of the stream for a short period, say, from one to three days. For the complete utilization of the power possibilities of a stream there should be storage enough to equalize the flow throughout the year. In making storage and pondage calculations the following relation is useful: 1 cubic foot per second for 24 hours will cover an acre with water 2 feet deep; that is, 1 cubic foot per second for 12 hours requires a storage of 1 acre-foot, or, to be precise, 0.992 acre-feet.

Calculation of Size of Storage Reservoir. — The following example illustrates the method recommended by Mead (*Water Power Engineering, N.Y., 1908*). Let Fig. 3 represent the hydrograph of a stream during the low-water period of the driest year. The area of each rectangular space represents 86,400,000 cu. ft. or 2000 acre-ft. Let it be required to find the capacity of the storage reservoir required to maintain a flow of 3000 sec.-ft. or over throughout the year. The maximum deficiency below 3000 sec.-ft. occurs between c and d and amounts to 3.25 rectangles or 6500 acre-ft., as shown by the cross-hatched area. A reservoir capable of supplying this quantity of water will also be able to supply the deficiency between a and b and between g and h, since the amount drawn from it during the interval ab will be restored during the interval bc and the amount drawn out during the interval cd will be restored during the interval dg, giving an ample supply of water to supply the deficiency during the interval gh. The actual capacity of the reservoir should exceed the 6500 acre-ft. by an allowance for evaporation, this allowance depending on the duration of the low-water periods, the time of the year, and the surface area of the reservoir.

Again, let it be required to find the capacity of the reservoir required to maintain a flow of 4000 sec.-ft. or over. In this case the entire interval from c' to h' must be considered, since the small amount of water stored during the intervals $d'e'$ and $f'g'$ is not sufficient to maintain the flow during the intervals $e'f'$ and $g'h'$. The total deficiency during the period $c'h'$ is 18 rectangles, shown by the cross-hatched area. The water stored during this interval, the unshaded portion above the 4000 line, is 4 rectangles. The difference, $18 - 4 = 14$ rectangles or 28,000 acre-ft., represents the net capacity of the reservoir, to which should be added an allowance for evaporation.

BIBLIOGRAPHY. — A complete bibliography up to 1908 is given in Mead's *Water Power Engineering*. Among the references there given may be noted the *Annual Reports of the U. S. Geological Survey; Water Supply and Irrigation Papers of the U. S. Geological Survey;* Hoyt and Grover, *River Discharge*, N. Y., 1907; numerous papers in the *Engineering News*. [L. E. MOORE.]

HYPERBOLIC FUNCTIONS. — (*See also Derivatives; Integrals; Series, Mathematical.*) Hyperbolic functions are an extension of the trigonometric functions to those cases where the use of the latter gives rise to imaginary or complex angles. From the relations,

$$\cos x = \frac{\epsilon^{jx} + \epsilon^{-jx}}{2}$$

$$\sin x = \frac{\epsilon^{jx} - \epsilon^{-jx}}{2j}$$

where $j = \sqrt{-1}$, it follows that, putting $x = jz$:

$$\cos jz = \frac{\epsilon^{z} + \epsilon^{-z}}{2} \qquad (1)$$

$$-j \sin jz = \frac{\epsilon^{z} - \epsilon^{-z}}{2} \qquad (2)$$

Expressions (1) and (2) are both real quantities when z is real, that is, when the angle jz is imaginary. The first expression is called the hyperbolic cosine of z, abbreviated and pronounced "cosh"; the second expression is called the hyperbolic sine of z, abbreviated sinh and pronounced "shin." Hence, using x for the variable,

$$\sinh x = \frac{\epsilon^{x} - \epsilon^{-x}}{2}$$

$$\cosh x = \frac{\epsilon^{x} + \epsilon^{-x}}{2}$$

The hyperbolic tangent, cotangent, secant and cosecant are defined as follows:

$$\tanh x = \frac{\sinh x}{\cosh x}$$

$$\coth x = \frac{\cosh x}{\sinh x}$$

$$\operatorname{sech} x = \frac{1}{\cosh x}$$

$$\operatorname{csch} x = \frac{1}{\sinh x}$$

The hyperbolic angle x is a number analogous to radians in circular measure; it is never expressed in degrees.

Period of the Hyperbolic Functions. — Adding 2π to an angle does not change the value of the trigonometric functions; they are therefore said to have a period equal to 2π radians. Hyperbolic functions, however, have no true period, but adding $2\pi j$ to the hyperbolic angle does not change the values of the functions; hence these functions have an imaginary period, $2\pi j$.

Table of Hyperbolic Functions.* — Below is given a table of hyperbolic functions.

* More complete tables of hyperbolic functions may be found in the *Smithsonian Mathematical Tables*, by G. F. Becker and C. E. Van Orstrand, Washington, 1909 and in *Tables of Complex Hyperbolic and Circular Functions*, by A. E. Kennelly, Harvard Univ. Press, 1914.

Example. — sinh 0.83 = 0.9286, cosh 0.83 = 1.3647, tanh 0.83 = 0.6805.

Approximate Formulas. — Note that for x less than 0.1,

$$\sinh x = x \text{ with an error of less than 0.2 per cent.}$$

$$\cosh x = 1 + \frac{x^2}{2} \text{ with an error of less than 0.09 per cent.}$$

For x greater than 6,

$$\sinh x = \cosh x = \frac{\epsilon^x}{2} = \frac{1}{2} \log_{10}{}^{-1} (0.43429\, x)$$

with an error of less than 0.01 per cent.

Anti-Functions. — If $a = \sinh x$, then x is the angle whose hyperbolic sine is a; this may be expressed symbolically

$$x = \sinh^{-1} a$$

which is read "x equals the angle whose hyperbolic sine is a." The angle x is also called the "anti-hyperbolic sine" or the "inverse hyperbolic sine" of a. Similarly for the other hyperbolic functions. (See *Trigonometric Functions, sub-heading Anti-functions.*) The following relations exist between the anti-hyperbolic functions and the natural logarithms:

$$\sinh^{-1} x = \log \left(x + \sqrt{x^2 + 1}\right)$$

$$\cosh^{-1} x = \log \left(x + \sqrt{x^2 - 1}\right)$$

$$\tanh^{-1} x = \frac{1}{2} \log \left(\frac{1 + x}{1 - x}\right)$$

Relations among Functions of the Same Angle. —

$$\cosh^2 x - \sinh^2 x = 1$$

$$1 - \tanh^2 x = \frac{1}{\cosh^2 x}$$

$$\coth^2 x - 1 = \frac{1}{\sinh^2 x}$$

$$\sinh(-x) = -\sinh x$$

$$\cosh(-x) = \cosh x$$

$$\tanh(-x) = -\tanh x.$$

See also the definitions given above.

Sum and Difference of Two Angles. —

$$\sinh(x + y) = \sinh x \cosh y + \cosh x \sinh y$$

$$\cosh(x + y) = \cosh x \cosh y + \sinh x \sinh y$$

$$\tanh(x + y) = \frac{\tanh x + \tanh y}{1 + \tanh x \tanh y}$$

$$\sinh(x - y) = \sinh x \cosh y - \cosh x \sinh y$$

$$\cosh(x - y) = \cosh x \cosh y - \sinh x \sinh y$$

$$\tanh(x - y) = \frac{\tanh x - \tanh y}{1 - \tanh x \tanh y}$$

Product of the Functions of Two Angles. —

$$\sinh x \sinh y = \tfrac{1}{2} [\cosh(x + y) - \cosh(x - y)]$$

$$\sinh x \cosh y = \tfrac{1}{2} [\sinh(x + y) + \sinh(x - y)]$$

$$\cosh x \sinh y = \tfrac{1}{2} [\sinh(x + y) - \sinh(x - y)]$$

$$\cosh x \cosh y = \tfrac{1}{2} [\cosh(x + y) + \cosh(x - y)]$$

Functions of Twice an Angle.—

$$\sinh 2x = 2 \sinh x \cosh x$$
$$\cosh 2x = \sinh^2 x + \cosh^2 x$$
$$\tanh 2x = \frac{2 \tanh x}{1 + \tanh^2 x}$$

Functions of Half an Angle.—

$$\sinh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{2}}$$
$$\cosh \frac{x}{2} = \sqrt{\frac{\cosh x + 1}{2}}$$
$$\tanh \frac{x}{2} = \sqrt{\frac{\cosh x - 1}{\cosh x + 1}}$$

Functions of Three Times an Angle.—

$$\sinh 3x = 3 \sinh x + 4 \sinh^3 x$$
$$\cosh 3x = 4 \cosh^3 x - 3 \cosh x$$
$$\tanh 3x = \frac{3 \tanh x + \tanh^3 x}{1 + 3 \tanh^2 x}$$

Relations between Hyperbolic and Trigonometric Functions.—

$$\sinh(jx) = j \sin x \qquad \sin(jx) = j \sinh x$$
$$\cosh(jx) = \cos x \qquad \cos(jx) = \cosh x$$
$$\tanh(jx) = j \tan x \qquad \tan(jx) = j \tanh x$$
$$\sinh^{-1} jx = j \sin^{-1} x \qquad \sin^{-1} jx = j \sinh^{-1} x$$
$$\tanh^{-1} jx = j \tan^{-1} x \qquad \tan^{-1} jx = j \tanh^{-1} x.$$

$$\cosh^{-1} jx = j \cos^{-1} jx = \log\left(x + \sqrt{1 + x^2}\right) - j\frac{\pi}{2}$$

Hyperbolic Functions of a Complex Angle.—

$$\sinh(x + jy) = \sinh x \cos y + j \cosh x \sin y = M\epsilon^{j\theta}$$

where $M = \sqrt{\dfrac{\cosh 2x - \cos 2y}{2}}$ and $\tan\theta = \dfrac{\tan y}{\tanh x}$.

$$\cosh(x + jy) = \cosh x \cos y + j \sinh x \sin y = N\epsilon^{j\phi}$$

where $N = \sqrt{\dfrac{\cosh 2x + \cos 2y}{2}}$ and $\tan\phi = \tanh x \cdot \tan y$.

$$\tanh(x + jy) = \frac{\sinh x \cos y + j \cosh x \sin y}{\cosh x \cos y + j \sinh x \sin y} = P\epsilon^{j\psi}$$

where $P = \sqrt{\dfrac{\cosh 2x - \cos 2y}{\cosh 2x + \cos 2y}}$ and $\psi = \tan^{-1}\left[\dfrac{\sin 2y}{\sinh 2x}\right]$.

$$\tanh^{-1}(A\epsilon^{j\alpha}) = B_1 + jB_2,$$

where $B_1 = \frac{1}{2}\tanh^{-1}\left[\dfrac{2A\cos\alpha}{1 + A^2}\right]$ and $B_2 = \frac{1}{2}\tan^{-1}\left[\dfrac{2A\sin\alpha}{1 - A^2}\right]$.

[W. A. Del Mar.]

ILLUMINATION, INTERIOR. — (*See also Illumination, Laws of; Illumination, Street; Vision, Laws of.*) The chief problems in interior illumination are: (1) to render visible certain objects or surfaces so as to avoid fatigue and injury of the eyes, and to enhance in effectiveness all operations dependent on good vision; (2) to reveal in their true values the architecture and decoration of interiors; and (3) to produce intrinsic artistic effects through the control of the color, intensity and direction of light. Engineering practice has been developed mainly with reference to the first of these problems, though the other two are often of chief importance and must at all times be considered. For a discussion of the hygienic aspects of illumination, see *Vision, Laws of.*

Reference Surfaces. — Illumination problems are usually worked out by reference to one or more planes or surfaces whose illumination can be taken as an index to the meeting of the general requirements. Unless special considerations dictate otherwise the plane selected is usually horizontal and at a height of from 2½ to 3 feet above the floor, corresponding with that of table tops, desks, counters, work benches, etc. In many cases other surfaces, as the floor, walls, faces of shelving, stacks of books, etc., are more significant than an arbitrarily chosen horizontal plane. The proper reference surface for the illumination of show windows is usually a surface inclined or curving upward from the base of the window. In many art galleries and on the stage of a theatre the proper reference planes are vertical. The most significant reference planes for any problem should be selected by a study of the special requirements.

Efficiency of Utilization. — The ratio of the luminous flux received by a reference plane to that produced by the light sources used for its illumination is known as the efficiency of utilization, or the utilization factor of the system. The light received by a reference plane is often termed useful flux to distinguish it from the total flux output of illuminants. The above terms may be very misleading if used indiscriminately, for the flux received by other surfaces than a reference plane is usually essential to the effectiveness of a system of illumination.

DIRECT, INDIRECT AND SEMI-INDIRECT ILLUMINATION. — Methods of illumination may be classified according to the manner in which light is delivered to the working surfaces. Direct light is that received directly from lamps and their accessory shades and reflectors. Indirect light is that received by reflection from some extended diffusing surface, as a ceiling or wall. Systems of illumination are either direct, indirect or semi-indirect. In the direct system the illuminants, including their reflectors and shades, are exposed and deliver a considerable part of their light in the direction of the reference areas. Indirect light from the walls and ceilings is received as an auxiliary component. In the direct system the lower surfaces of a room have the highest illumination. The illuminants produce shadows, the sharpness of which vary inversely with the diffusion of light. Polished or glazed surfaces may produce an annoying glare in certain lines of vision, due to the specular reflection of the exposed light sources. Unshaded lamps are a source of great annoyance and fatigue. The shadows of direct lighting intensify and in some cases exaggerate relief effects, and may be made to serve as aids to vision where color differences are slight.

The indirect system of lighting conceals all primary sources and distributes light from large diffusing surfaces, usually white ceilings and upper walls. The upper surfaces of the room have the highest illumination. Shadows are eliminated or greatly reduced in intensity. Glare from visible light sources is avoided and the specular reflection of glazed surfaces is generally inappreciable. The uniformity of illumination on the lower surfaces of a room is very great. The great diffusion of light in the indirect system is frequently stated to closely reproduce daylight. This is not strictly true, however, for daylight though diffused is directed and gives a diminishing gradation of illumination from the

lower to the upper part of the room. The faintness of shadows with indirect lighting tends to flatten relief effects.

Semi-indirect lighting mediates between the two extremes. The light sources are shielded from direct vision by inverted bowl reflectors of translucent glass, which transmit downward a moderate amount of direct light and reflect the remainder to the ceiling. There is an absence of agreement as to the most favorable ratio of direct to indirect light. It is desirable that the brightness of the translucent bowls shall equal or slightly exceed that of the ceiling. The direct component should be adequate to create a normal relief effect and to bring up the illumination of working surfaces to a value above that of the background. The experiments of T. W. Rolph (*Trans. Ill. Eng. Soc., Vol. 7, pp. 234 and 549*) indicate that very satisfactory results are secured with a direct component of about 15 per cent.

In comparing the various systems outlined a large allowance must be made for differences of psychological effect. Critics of indirect lighting assert that the complete elimination of shadows and the reversal of the customary gradation of brightness are very annoying, distract attention, distort the sense of distance and promote fatigue. Others find the same aspects advantageous and hold that the elimination of glare by specular reflection outweighs other considerations. The unfavorable qualities of direct lighting avoided by the indirect method are largely abuses due to unshaded and poorly-located lamps rather than inherent faults. Several investigators have studied the relative illumination intensities required for equally effective vision by the different systems. The observed differences are inconsistent and are probably due to incidental conditions, such as unequal contrast between working surfaces and backgrounds and to direct glare from visible light sources. It is agreed that with equal skill in design direct lighting ranks first, semi-indirect lighting second and indirect third in efficiency of utilization.

Desirable Color and Direction of Illumination. — There is no well-defined color standard in illumination. Daylight white is desirable for exact color matching and for color printing, but is not essential for other purposes. The Moore carbon-dioxide tube reproduces daylight white with great fidelity and also closely approaches daylight in diffusion. True white may also be obtained from arc and incandescent lamps by the aid of color screens to filter out the hues present to excess. Magnetite arcs and nitrogen-filled tungsten lamps are best adapted to this process. Of the illuminants in common use the white flame arc and the intensified carbon arc give the nearest approach to white. The nitrogen-filled tungsten lamp surpasses other incandescent lamps in whiteness. The ordinary tungsten lamp and the best grade of Welsbach mantles are somewhat unlike in tone, but differ about equally from white. Light having a predominant hue, as that of the mercury arc, is superior for the revelation of fine detail. Light of amber tint is regarded as softer and warmer than light of bluish or greenish tint. The tint of indirect light is modified by the color of the reflecting walls and ceilings.

In determining the direction of light the avoidance of glare and shadows in the visual field is most important. In the display of art objects and architectural details the dominant direction should be carefully chosen to produce a correct sense of relief. An inversion of light and shade by artificial light as compared with daylight is especially to be avoided. Head and hand shadows are especially to be avoided in reading and in mechanical operations. The old rule of light from above the left shoulder is an excellent one. It has been found advantageous in schoolrooms, offices and drafting rooms to locate desks and tables with the windows to the left of those at work and to displace the artificial light sources from symmetrical positions toward the windows in order to give a directive effect similar to daylight.

QUANTITY OF LIGHT AND NUMBER OF ILLUMINANTS FOR DIRECT LIGHTING. — The intensities of illumination required for various purposes are given in the article on *Vision, Laws of*. The simplest illumination problems are those in which a uniform illumination of E foot candles is desired on a horizontal plane of A square feet. The useful flux required is then A times E. If a factor of utilization K is known or assumed for the conditions of the room the total flux F, in lumens, to be produced by the illuminants is

$$F = \frac{AE}{K}.$$

The total watts of electric power or the cubic feet per hour of gas consumption to produce the required flux is found by dividing the required flux by the lumens per watt or per cubic foot per hour given by the type of light source under consideration.

For detailed data on the lumens per watt or per unit of gas consumption given by various illuminants, see *Lamps, Incandescent; Lamps, Arc;* and *Gas Lighting.*

Factors of Utilization vary with the shape of the room, the absorption in reflectors and shades, the form of light distribution of the illuminants and the reflecting efficiency of the walls and ceilings. Their values cannot be reduced analytically. When the ratio of room height to smallest floor dimension is great the absorption light by walls and ceilings is evidently greater than under the opposite conditions. Light-colored walls and ceilings and a strong downward light concentration by efficient reflectors are factors which increase utilization efficiency. Cleanliness of lamps, reflectors, globes and walls is of great importance to the maintenance of utilization efficiency. The following values have been compiled empirically by J. R. Cravath from the data of numerous reliable illumination tests.

FACTORS OF UTILIZATION

Equipment	Ratio of shortest floor dimension to height of room	Utilization factor, per cent		
		Light ceiling, light walls	Light ceiling, dark walls	Dark ceiling, dark walls
Direct system	3 or more	55 to 65	50 to 60	....
Prismatic or opal reflectors near ceiling	1 to 2.5	50 to 60	45 to 55	30 to 40
Direct system	3 or more	35 to 45	30 to 40	....
Frosted globes near the ceiling	1 to 2.5	30 to 40	25 to 35	15 to 25
Direct system	3 or more	40 to 50	37 to 47	....
Bare lamps at ceiling	1 to 2.5	38 to 48	30 to 40	20 to 30
Indirect system	3 or more	15 to 25	....	....
Lamps in enamelled coves	1 to 2.5	10 to 20	....	....
Indirect system	3 or more	34 to 44	32 to 42	....
Lamps in inverted bowl reflectors	1 to 2.5	30 to 40	25 to 35	....

C. E. Clewell, *Factory Lighting*, p. 17, reports average utilization efficiencies found by him in extensive tests of direct lighting as follows:

	Per cent
Low offices	27.1
Fairly high factory offices	27.4
Low factory space	27.0
Medium-high factory space	30.8
Fairly high factory space	29.1

The illuminants were tungsten lamps in standard reflectors. The measurements were taken in intervals between cleaning and renewals.

Estimates of Effective Flux. — The preliminary estimates for most problems in interior illumination can be made with fair accuracy from the following tables, which give empirical values based on laboratory and service tests. (*See Trans. Ill. Eng. Soc., Vol. 3, p. 518 and Vol. 4, pp. 321, 849, 885.*)

LUMENS ON REFERENCE PLANE PER WATT, ELECTRIC LAMPS

(Lamps and glassware are assumed to be clean and at a height above the reference plane not exceeding 15 feet.)

Lamp	Reflector or globe	Ceiling	Walls	Effective lumens per watt
Tungsten	Silvered reflector	Light	Light	6.1
Tungsten	Prismatic reflector	Light	Light	5.0
Tungsten	Prismatic reflector	Light	Dark	4.0
Tungsten	Enamelled reflector	Light	Light	3.5
Tungsten	Enamelled reflector	Light	Dark	3.0
Gem	Prismatic reflector	Light	Light	2.2
Gem	Prismatic reflector	Light	Dark	1.8
5-amp. d-c. arc	Opal inner globe	Light	Medium	2.0
Mercury arc	Enamelled reflector	Medium	Medium	5.5

LUMENS ON REFERENCE PLANE PER CUBIC FOOT OF GAS PER HOUR

(Lamps and glassware assumed to be clean; new mantles; height above reference plane not exceeding 15 feet; gas, 700 B.t.u. per cu. ft.)

Lamp	Reflector or globe	Ceiling	Walls	Effective lumens per cu. ft. per hour
Upright mantle	Opal globe	Light	Light	49
Upright mantle	Opal globe	Light	Dark	27
Upright mantle	Opal reflector	Light	Light	85
Upright mantle	Opal reflector	Light	Dark	50
Inverted mantle	Prismatic reflector	Light	Light	140
Inverted mantle	Prismatic reflector	Light	Dark	128
Inverted mantle	Roughed ball	Light	Light	101
Inverted mantle	Roughed ball	Light	Dark	75
4-mantle upright arc	Alabaster globe	Light	Light	66
4-mantle upright arc	Alabaster globe	Light	Dark	48
5-mantle inverted arc	Alabaster globe	Light	Light	87
5-mantle inverted arc	Alabaster globe	Light	Dark	65

Location of Illuminants. — Having found the total wattage or rate of gas consumption to be provided the next step is to select a proper number and arrangement of lamps. It is seldom possible to produce a uniform illumination from a single source along a radial distance greater than the height of the lamp above the plane. It is practically impossible to avoid shadows from a single central unit. A symmetrical and uniform spacing of several lamps is necessary for uniform illumination by direct lighting. The use of many small units with close spacing promotes uniformity and reduces shadows. The use of few large units widely spaced promotes economy. In many cases a compromise must be made between the two plans. The various spacing schemes in vogue are largely reducible to three types, viz.: (*a*) a long and narrow room with a single row of lamps on the center line, the spacing about equal to the width of the room; (*b*) a rectangular room divided into squares with lamps located at the center of each, the width of each square preferably not greater than twice the height of suspension of the lamps above the reference plane; (*c*) lamps at corners of equilateral triangles and spaced at not more than twice suspension height, spacing to walls being half the spacing from lamp to lamp. Plans of these schemes are shown in Fig. 1.

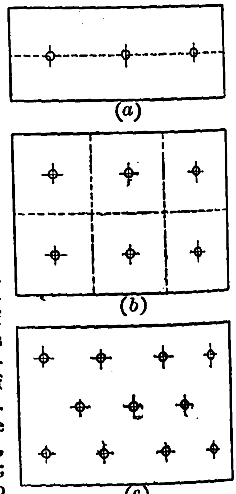

Fig. 1. Spacing Schemes for Direct Lighting

In determining the spacing of lamps very careful attention should be given to the structural divisions of ceiling space. Each bay or division may properly have a symmetrical spacing as this will greatly reduce the shadows cast by pillars and beams. It is possible to secure a very uniform direct illumination from any unit giving a symmetrical distribution if a certain critical ratio of height to spacing is exceeded. The value of this critical ratio depends on the form of light distribution, as shown by the prototype curves of Fig. 16 in the article on *Illumination, Laws of*. Holophane reflectors for tungsten lamps are made in three types, viz., extensive, for wide spacing, the critical ratio of height to spacing being 0.5; intensive, for medium spacing, the critical ratio being 0.67; focussing, for high suspension and close spacing, the critical ratio being 1.33. A spacing chart for Holophane and for X-ray reflectors is shown in Fig. 2. With a ratio of height to spacing below the critical value the light is spotted. With a higher ratio the illumination remains uniform, but with some loss of utilization efficiency, due to the increased absorption of light by the walls. The efficiency does not follow an inverse square relation to the height in any case, and is but slightly affected when the walls are of light color and the reflectors give a strong downward distribution. In very large rooms the effect of suspension height on utilization efficiency is trifling. The suspension height should if possible be sufficient to remove the light sources from direct lines of vision.

Single-lamp Units vs. Clusters. — A single-lamp electric unit is less expensive to install and maintain and is usually more efficient than a cluster of several lamps having the same total candle-power. The cross-absorption of light in clusters may be as high as 10 per cent. Gas clusters of the so-called "arc" type have an advantage over single-mantle lamps in heat conservation and facility of remote control. In fact, single-mantle lamps offer a small range candle-power.

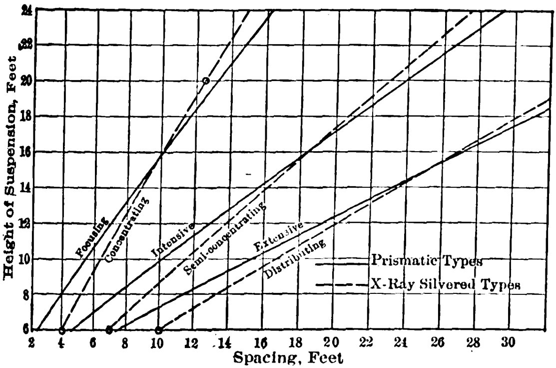

Fig. 2. Maximum Spacing of Reflectors for Uniform Illumination

Point-by-point Calculations of Illumination. — Such calculations are very useful in checking up the distribution of illumination. The method of calculating is described in the article on *Illumination, Laws of.*

METHODS OF INDIRECT LIGHTING. — The process of determining the power required to produce a given illumination of any area by indirect means is the same as that outlined above for direct lighting, a suitable value of the efficiency of illumination being used. There are two types of indirect lighting, the bowl and the cove. Indirect lighting from suspended bowls affords greater flexibility in light distribution than cove lighting and is capable of producing more uniform and efficient effects. The efficiencies of utilization obtainable with indirect bowl lighting are given by the National X-ray Reflector Co. as ranging from 0.20 to 0.32 with dark walls and from 0.24 to 0.34 with light walls for ratios of minimum floor dimension to ceiling height of from 1.0 to 3.5; the ceilings are assumed to be painted white and an allowance of 20 per cent for loss of light by dust and lamp aging is included in these values. The proper suspension height for indirect bowl units is approximately three-quarters the height of the room. In spacing the units a symmetrical arrangement at the centers of ceiling squares is highly desirable. The maximum dimension of such a spacing square or rectangle should not exceed a certain ratio to the ceiling height for the best results, viz., for ceiling heights below 12 feet, the maximum ratio is 1.5; for ceiling heights from 12 to 17 feet, the maximum ratio is 1.75; above 17 feet, 2.0.

In the cove type of indirect lighting the lamps are placed in the trough of the cove with axes horizontal, and are backed with a trough reflector of high efficiency. Light is thus thrown to the upper surface of the cove and from it reflected into the room. Cove lighting about the base of a flat-domed ceiling is somewhat more effective than with a flat ceiling. Dust tends to collect on lamps and reflecting surfaces and seriously reduces the average efficiency of the system.

Illuminants for Indirect and Semi-indirect Lighting. — The enclosed carbon arc has been extensively used in semi-indirect and indirect lighting systems. The arc should be arranged with the positive carbon below and the enclosing globe should be of clear glass. The reflector for wholly indirect arc lighting is an inverted flat cone of enamelled metal. A translucent opal glass reflector resembling an inverted bell is placed beneath the arc for semi-indirect arc lighting. The latter type of unit is usually provided with an enamelled

diffusing reflector above the lamp. This reflector has a surface of concentric ripples, which serve to improve the symmetry of light distribution from the wandering crater of the arc. While somewhat less efficient than direct lighting these methods of using arcs produce superior results, due to the adequate diffusion and improved steadiness of the light. Indirect lighting with carbon arcs is inferior in efficiency to similar systems using tungsten lamps, especially those of the nitrogen type. The nitrogen-filled tungsten lamp is excellently adapted to use in large indirect lighting fixtures, but its extreme brilliancy renders it unsuited to direct lighting without a diffusing envelope.

MAINTENANCE OF EFFICIENCY. — Loss of efficiency in lighting systems may be due to the aging of lamps, failure to maintain proper lamp voltage, and the collection of dirt on lamps, reflectors, shades and the reflecting surfaces of the room. Systematic inspection and cleaning are essential if the most economical results are to be secured from large systems. Lamps should be replaced when the bulbs become badly blackened. Globes and reflectors should be cleaned at least once a month for most effective service. C. E. Clewell, *Factory Lighting*, p. 48, reports that a depreciation test of an office installation of tungsten lamps in glass reflectors showed a gradual loss of efficiency which reached a steady value of 19 per cent in 30 days. A similar test in a factory showed a gradual reduction of efficiency which reached a steady value of 48 per cent in 24 days. Arc lamps depreciate in efficiency between trimmings and cleaning from 15 to 30 per cent due to the collection of ash on the inner globes. Arcs are relatively little affected by outside dirt and are quite generally preferred to incandescent lamps in very smoky and dusty locations. Careful attention should be given to the ceilings of rooms with indirect lighting to prevent the accumulation of dust and the loss of whiteness.

SPECIAL LIGHTING PROBLEMS. — In art galleries for the exhibition of paintings a moderate general illumination should be provided from sources giving good diffusion. Paintings should be illuminated by direct light received from concealed sources several feet in front of, and slightly above, the level of the paintings. The direction of this light should be carefully studied to avoid specular reflection from glass or glossy portions of paint. For good color effects the light should approach as near as possible the color of daylight. Sculpture is effectively lighted by indirect or semi-indirect methods, but the illuminants may properly be suspended along the side of the room containing the windows to obtain directed illumination sufficient to reproduce the relief effects of daylight.

In ritualistic churches it is important to produce a brilliant illumination of the sanctuary with a large vertical component by means of concealed lamps. The distribution of lamps in the nave should be chosen to reveal the architectural effects of the structure. Large and low-hanging pendant fixtures in the axis of the room are generally undesirable. Bracket clusters, groups of small incandescent lamps worked into the capitals of pillars, and small pendant fixtures in the arcades can be used with excellent effect. In non-ritualistic churches adequate reading light is desired at all pews. Brilliant light sources in the field of vision are especially to be avoided. If a balcony is used the light sources should be hung high and thoroughly diffused. The platform should be brightly lighted, but by light sources not visible to the auditors.

Stages and platforms in theatres and public halls should have high illumination, especially in vertical planes, but the light sources should be entirely concealed.

Office desks should be lighted with a view to preventing head and hand shadows and glare from glossy surfaces. Well-diffused general lighting with a dominant component from above the left shoulder is perhaps the best solution of the

problem. When local lighting is required a pendant lamp in a deep conical reflector of green flashed opal glass suspended at a height above the desk of 2 to 2.5 feet and near the left edge of the desk will fulfill all requirements.

Show windows should be lighted by entirely concealed light sources placed at or above the upper edge of the window. Illumination should be designed for a surface which is inclined or concave upward from the lower edge of the window. On brilliantly-lighted business streets a very high illumination of 20 foot-candles or more is necessary to attract attention. On less brilliantly-lighted streets the illumination may be reduced in proportion. The lamps should be backed by highly efficient reflectors. The form of light distribution desired depends on the dimensions of the window, the degree of concentration increasing with the ratio of the height to the depth of the window space. Tests reported by H. B. Wheeler (*Ill. Eng. Soc., Vol. 8, p. 555*) show that utilization efficiencies on the trim surface depend on the ratio of height to depth of the window space. The results cited range from 58 per cent for a height to depth ratio of 1, to 42 per cent for a ratio of 2. Show cases in the aisles of stores afford a problem akin to show-window lighting. In brightly-lighted rooms the illumination of the interior of the case must be very high to gain attention. Entirely concealed lamps are required and these may properly be placed in shallow trough reflectors in the upper dihedral angles of the case. Tubular and linolite lamps are appropriate, due to their space economy.

[W. E. WICKENDEN.]

ILLUMINATION, LAWS OF. — (*See also Angles; Photometric Quantities; Vision, Laws of.*) Light may come from either a point source or a finite source. Serious errors may result from the application of the laws of point sources to the illumination from finite areas, due to the non-parallel rays. The errors are negligible, however, when the distance separating the light source and the illuminated surface exceeds ten times the greatest projected dimension of either in a plane normal to the mean direction of light. For definitions of quantities see *Photometric Quantities*.

LIGHT FROM A POINT SOURCE. — When the light comes from a point source the "inverse square" and the "cosine" laws apply:

Inverse Square Law. — The illumination from a point source varies inversely as the square of the distance from the source. This law rests on the geometrical fact that the spherical area intercepting light flux varies as the square of its radius.

Cosine Law. — The illumination received by an element of surface varies as the cosine of the angle of incidence. The basis of this law is also geometrical. These two laws may be stated thus:

$$E = \frac{I \cos \alpha}{l^2},$$

where E = intensity of illumination in foot-candles; I = intensity of the light source in candle-power; α = angle of incidence of light on the illuminated area; and l = distance in feet from the light source to the point illuminated.

Calculation of Light Flux and Mean Intensities from Point Sources. — Let I_θ be the mean intensity of a light source at an angle θ from the axis about which the light distribution is symmetrical, usually the vertical axis. The flux within an elementary zone at this angle of inclination is then

$$dF = I_\theta \, d\omega = 2 \pi I_\theta \sin \theta \, d\theta.$$

The flux within any finite zone about the axis of distribution may be found by integration when the law of distribution is known. In general, however, it is necessary to employ graphical means of integration for this purpose. The mean intensity within any finite zone cannot be found by direct average, since each beam bears a weight proportional to $\sin \theta$. The graphical methods described below are the most serviceable.

Protractor Methods. — This method is adapted to quick approximations of mean zonal, mean hemispherical and mean spherical intensities. The method assumes a sphere of light distribution divided into zones of equal solid angular content, i.e., of equal altitude. A direct average of the mean intensities of the several zones gives the general mean for all the zones included, since each component zone bears equal weight. For convenience it may be assumed generally that the mean intensity in any zone agrees closely with that at the angle which bisects the area of the zone. Fig. 1 shows a convenient subdivision of the sphere based on this assumption. To obtain the mean spherical candle-power the intensities at all the angles indicated by radial lines are averaged. This result multiplied by 2π gives the total flux from the source. Similarly the average of the intensities at the angles indicated in either hemisphere gives the mean hemispherical candle-power, which may be multiplied by π to obtain the hemispherical light flux. The average taken at the three lowest positions gives the mean intensity

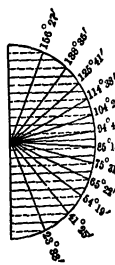

Fig. 1.

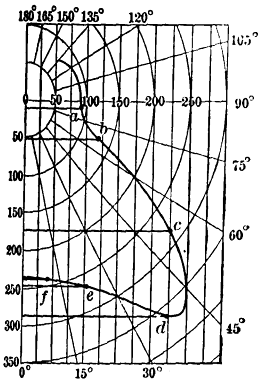
below 60° and this value, multiplied by $\pi/2$, gives the flux within the $0° - 60°$ zone. For convenience in practice a transparent protractor may be prepared with the reference angles shown by black lines. This protractor may be placed over the polar distribution curve and the values for averaging read off directly. The accuracy of the method depends on the regularity of the distribution curve.

Flux-o-lite Diagram. — (Fig. 2.) This diagram is constructed from the polar distribution curve by drawing vertical reference lines tangent to the candle-power circles, with uniform intermediate divisions as desired. To find the flux within any zone the horizontal projection of the mid-zone intensity is measured on the scale created by the vertical reference lines. Multiply this value by the constant which corresponds to the arc of the zone in the accompanying table.



$a = 90$ $b = 118$ $c = 225$

$d = 223$ $e = 103$ $f = 41$

Sum $= 800$ $F_{lh} = 800 \times 1.64 = 1312$

$I_{mlh} = 1312 \div 6.2832 = 208.8$

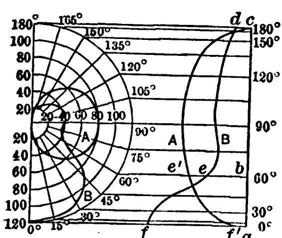
Fig. 2. Flux-o-lite Diagram

The flux within any angular limits is found by summing the components from the several zones included. For accuracy a large number of small component zones should be taken. For proof, it is readily shown that the solid angular content of any zone is equal to

Arc of zone, degrees	Constant
5	0.548
10	1.098
15	1.64
20	2.18
25	2.72
30	3.25

$$4\pi \sin\theta \sin\frac{n}{2},$$

where n is the arc of the zone in degrees and θ the bisecting angle measured from the vertical axis. The above constants in each case equal $4\pi \sin n/2$ and the horizontal projections read from the diagram are in each case equal to the assumed mean intensity of the zone times the sine of the bisecting angle.



A = Bare 80 c.p. Lamp B = Same with Reflector

Area $abce'f' = 15000$ For A, $F_s = 785.4$ $I_s = 62.5$

Area $abcdef = 12080$ For B, $F_s = 632.9$ $I_s = 50.3$

Absorption of Reflector $= 152.5 = 19.52\%$

Fig. 3. The Rousseau Diagram

Rousseau Diagram. — (Fig. 3.) The Rousseau diagram admits of considerable accuracy, but involves the measurement of area. The arcs of the several zones of distribution are projected horizontally on the line abc. The intercepts equal the altitudes of the several zones and are therefore proportional to their several solid angular contents, with a total abc equal to 4π. On each projection line is laid off from abc a length equal to the radius of the polar

curve at the corresponding angle. The terminal points are then connected by the smooth curve *def*. The area *abcdef* so inclosed represents the total flux, since

$$\text{Area } abcdef = \int_0^{4\pi} I\, d\omega = 4\pi I_s.$$

The total flux is

$$F_s = \frac{4\pi \times \text{area } abcdef}{\text{length } ac}.$$

The flux in any zone, e.g., between 0° and 60°, is

$$F_z = \frac{4\pi \times \text{area } abcf}{\text{length } ac}.$$

The mean intensity between any angular limits is equal to the portion of the area *abcdef* between those limits divided by the corresponding portion of the base line *abc*. This method is to be preferred to the others outlined where accuracy of a high order is desired, as in the measurement of the light absorption of reflectors, globes, shades, etc. In such cases the number of points of the photometric distribution curve determined by direct measure and referred by projection to the line *def* should be as large as practicable.

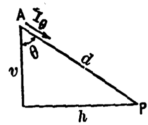


Fig. 4.

Calculation of Illumination at Points.—In Fig. 4 let A be the location of an illuminant and P a point at which the illumination from A is to be determined. The three most important cases of this problem refer respectively to the illumination of elements of surface at P located in horizontal and vertical planes and in a plane normal to the light path AP. From the laws of inverse squares and of cosines (*see above*) the horizontal illumination at P is

$$E_h = \frac{I_\theta \cos\theta}{d^2} = \frac{I_\theta \cos^3\theta}{v^2}.$$

The vertical illumination at P is

$$E_v = \frac{I_\theta \sin\theta}{d^2} = \frac{I_\theta \sin^3\theta}{h^2}.$$

The normal illumination at P is

$$E_n = \frac{I_\theta}{d^2} = \frac{I_\theta \cos^2\theta}{v^2} = \frac{I_\theta \sin^2\theta}{h^2}.$$

Calculations of this type are facilitated by a chart (Fig. 5) showing the value of θ for various values of v and h, and by tables giving the values of the illumination constants $\cos^3\theta/v^2$, $\sin^3\theta/h^2$, and $\cos^2\theta/v^2$ for various values of v and h. Such tables are given below.

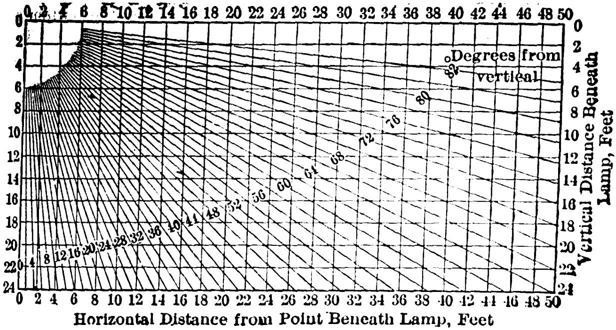

Fig. 5. Angle of Effective Beams for Point-by-point Calculations

50	......	......	......	......	......	......	0.00010	0.00011	0.00012	0.00013

The horizontal illumination at any point equals the intensity of the light source in its direction (see Fig. 5) multiplied by the constant in the above table

corresponding to its location. With a few exceptions near the bottom of the table, direct interpolations are correct to within 2 per cent. To compute vertical illumination at any point, exchange the vertical and horizontal distance components and use the constant so found.

The normal illumination at any point equals the intensity of the light source in its direction (see Fig. 5) multiplied by the constant in the above table corresponding to its location.

Calculation of Solid Angle Subtended by Illuminated Area. — In many cases it is desired to compute the total flux of light which falls upon a plane area from an approximate point source. This problem resolves itself into two elements, (1) to determine the mean intensity acting toward the illuminated plane, to which the methods previously described apply, and (2) to determine the solid angle subtended by the area illuminated at the source of light. The following theorems apply to the latter problem.

The solid angle subtended by a circle with the light source in its axis (Fig. 6) is

$$\omega = 2\pi\,(1 - \cos\alpha).$$

The solid angle subtended by a rectangle, one corner of which is directly beneath the source of light (Fig. 7), is

$$\omega = \tan^{-1}\frac{ac}{hd}.$$

When the projection of S falls on one edge of the area, the latter may be divided into two rectangles to meet the above theorem. When the projection falls within the area, the area may be divided into four such sections. When the projection falls outside ac in Fig. 7, the surface may be extended to meet the theorem and the solid angle subtended by the extension substracted from that of the combined areas.

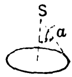

Fig. 6.

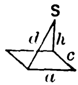

Fig. 7.

LIGHT FROM FINITE SOURCES. — Under conditions pointed out in connection with point sources, finite sources may be treated as point sources without appreciable error. When those conditions are not met, illumination problems may be solved by the aid of the following theorems.

Lambert's Cosine Law. — A true diffusing surface emits light in any direction with an intensity proportional to the cosine of the angle of emission, measured from the normal to the source. Unless especially prepared, reflecting and transmitting surfaces deviate from this law to some degree, depending on surface glaze and the nature of the translucent medium. In the following theorems true diffuse emission is assumed for each element of surface.

Total Light Emitted by a Plane Area A, having a surface brightness of b units of intensity in the normal direction, is

$$F = \pi A b.$$

Illumination Due to a Disk Source, having a brightness of b.

(a) At a point P under the disk in a plane parallel to the disk (Fig. 8) the illumination is

$$E = \frac{\pi b}{2}\cot\theta\,(\beta + 2\theta - \alpha).$$

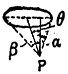

Fig. 8.

Fig. 9.

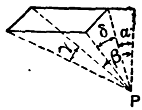

Fig. 10.

(b) In the special case where point P is in the axis of the disk (Fig. 9) the illumination is

$$F = \pi b \sin^2\alpha.$$

Illumination Due to a Rectangular Source, having a brightness of b.

(a) The illumination in a plane parallel to the source at a point under one corner of the source or one edge extended (Fig. 10) is

$$E = \frac{b}{2}[\delta\cos\alpha - \gamma\cos\beta].$$

(b) When the projection of the point P lies within the source, the source may be subdivided into rectangles and each solved according to case (a).

(c) When the projection of P lies without the area and not on one edge extended, a solution is made by enlarging the rectangle to meet case (a) and subtracting the solution for the part added from that for the entire extended area.

(d) The illumination in a plane normal to the source at a point under one corner of the source (Fig. 11) is

$$E = \frac{b}{2}\left[\tan^{-1}\frac{c}{h} - \frac{h}{d}\tan^{-1}\frac{c}{d}\right].$$

Extensions of this theorem may be made in a manner analogous to that suggested for cases (b) and (c) above.

Illumination Due to the Hollow Interior of a Dome, whose lower boundary is a circle and whose surface brightness is b. The solution of this case is

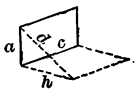

Fig. 11.

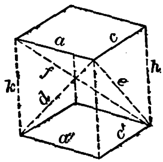

Fig. 12.

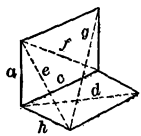

Fig. 13.

identical with that for a circular disk equal in area to the base of the dome and having the same brightness; see Fig. 9.

Flux Received by a Rectangular Area from a Similar and Parallel Area, having a brightness of b (Fig. 12).

$$F = 2\,b\left[ac\tan^{-1}\frac{a}{e} - ah\tan^{-1}\frac{a}{h} + cd\tan^{-1}\frac{c}{d} - ch\tan^{-1}\frac{c}{h} + \frac{h^2}{2}\log_e\frac{e^2d^2}{h^2f^2}\right],$$

when $$a = c = h,\ F = \frac{a^2\pi b}{5} = 0.6283\ a^2b.$$

Flux Received by a Rectangular Area from an Adjacent Normal Area of the same length, having a brightness of b (Fig. 13).

$$F = b\left[ah\tan^{-1}\frac{a}{h} - ad\tan^{-1}\frac{a}{d} + ac\tan^{-1}\frac{a}{c} + \frac{a^2}{2}\log_e\frac{e^2f^2}{a^2g^2} + \frac{e^2}{4}\log_e\frac{g^2}{e^2}\right.$$
$$\left. + \frac{a^2}{4}\log_e\frac{a^2}{f^2} + \frac{c^2}{4}\log_e\frac{c^2}{f^2} + \frac{h^2}{4}\log_e\frac{h^2}{d^2} + \frac{c^2}{4}\log_e\frac{g^2}{d^2}\right],$$

when $$a = c = h,\ F = \frac{a^2\pi b}{5} = 0.6283\ a^2b.$$

Light Flux Within an Inclosure. — If an entirely inclosed space is surrounded by walls having a reflection coefficient of r and a flux of light equal to F is emitted within this space by a light source, the total flux within the space due to direct emission and multiple reflection is

$$\Sigma F = F + Fr + Fr^2 + Fr^3 + Fr^4 + \ldots = F/(1-r).$$

In computing the total illumination of areas in rooms due to direct and indirect illumination this expression is of limited application due to the unequal reflection coefficients of the various surfaces. McAllister (*see Elec. Wld., Vol. 52, p. 1158*) has suggested a method of calculation based on the absorption of light by various surfaces, which rests upon the principle that the light absorbed by each surface equals the total flux received by it multiplied by its absorption coefficient, and that the total flux so absorbed equals the total flux emitted by the light sources. That is, given a room bounded by six surfaces whose areas are respectively A_1, A_2, A_3, etc., whose absorption coefficients are respectively a_1, a_2, a_3, etc., and

which are to be illuminated to respective intensities of E_1, E_2, E_3, etc., the total flux required of light sources is

$$\Sigma F = E_1 A_1 a_1 + E_2 A_2 a_2 + E_3 A_3 a_3 + \text{etc.}$$

STANDARD FORMS OF LIGHT DISTRIBUTION FOR UNIFORM ILLUMINATION. — The most important phase of this problem, viz., the uniform illumination of a horizontal plane by one and by many illuminants, will be outlined. The form of light distribution required to obtain uniform horizontal illumination from a single lamp is found by reversing the expression for horizontal illumination,

$$E_h = \frac{I\theta \cos^3\theta}{v^2} \qquad \text{to} \qquad I\theta = \frac{E_h v^2}{\cos^3\theta},$$

taking E_h and v as constants. The resulting form of polar curve for various ratios of the limiting horizontal distance h' to v are shown in Fig. 14. It is apparent that practical difficulties limit the range of application of this method. The more general case must be solved by the use of a considerable number of lamps uniformly spaced above the area illuminated. The type of horizontal illumination curve shown in Fig. 15 adequately meets this condition, as shown by the resultant illumination curves along the side and diagonal of the square included by the points directly under four equally spaced lamps. To obtain the form of illumination curve shown for various ratios of horizontal spacing s to vertical distance to the lamps v, the forms of light distribution shown in Fig. 16 are required.

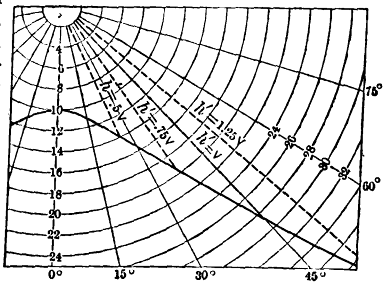

Fig. 14. Light Distribution Required to Obtain Uniform Horizontal Illumination from One Source

The ratios of spacing to height indicated in the figure are to be considered as the maximum ratios with which uniform illumination is obtained. With smaller ratios the uniform condition still exists. With a fixed spacing varying the height within the limit imposed by the ratio affects neither the uniformity nor the intensity of illumination, except in that portion of the room lying outside the outer row of lamps. By aid of well-designed reflectors it is possible to closely approximate the typical distribution curves for certain ratios of spacing to height and this ratio is important as a criterion in the selection of reflecting devices.

ILLUMINATION, STREET. — (*See also Illumination, Interior; Illumination, Laws of; Lamps, Arc; Lamps, Incandescent; Lighting Plants.*) Street lighting is intended to promote public safety, facilitate travel and business, and reveal architectural effects during hours of natural darkness. Experience shows that good street lighting attracts traffic and stimulates retail trade. The most important factors affecting the degree of street illumination required are the density of traffic, prevalence of retail business, degree of police supervision needed and the architectural importance of the thoroughfare. In moderate and dim light vision depends primarily on differences of brightness and is but slightly assisted by color distinctions. Objects may be seen directly and in some detail against a darker background, but are seen in mass or silhouette against a brighter background.

Requirements of Street Lighting. — The most important streets require sufficient illumination for direct and detail vision to clearly reveal vehicles, persons, obstructions, irregularities of the pavement, and to permit the easy reading of timepieces and addresses, which calls for an average of about 0.1 foot-candle and a minimum of 0.05 foot-candle on the most important working surfaces. Uniform illumination without deep shadows, which may be obtained by well-diffused light sources with fairly close spacing, is highly desirable on important streets.

Secondary streets with moderate evening traffic and orderly conditions require greater illumination at intersections than at intermediate points. The silhouette aspect of vision is very important in such streets and emphasizes the need of fairly bright and even roadway illumination without spots of deep shade from foliage. An average illumination of 0.05 foot-candle and a minimum of 0.02 meet the reasonable requirements of such streets. In this range of intensities the eye is highly susceptible to glare. Brilliant light sources without diffusing globes and suspended at a low level often largely defeat their purpose under these conditions.

Minor streets with scattered buildings and infrequent travel require mainly beacon lighting, equivalent in intensity to moderate moonlight, or normal illumination varying from a minimum of 0.01 foot-candle to an average of 0.03. At such low intensities the need of good diffusion at light sources is most acute, but is quite generally neglected for reasons of supposed economy.

Reference Planes — Street illumination in America is usually referred to normal reference planes (i.e., perpendicular to the light rays), and to horizontal planes in Europe. There is wide diversity in the elevation of reference planes, the most common levels being that of the pavement and that of a plane four feet above the pavement. The use of normal planes of reference takes satisfactory account of the light from but one source, while it is possible to sum up the light received from all directions on horizontal planes. It is evident from the cosine law of incidence that the horizontal illumination from low and distant lamps is less in magnitude and more difficult of exact measurement than the normal component. Normal illumination is a more useful index to the visibility of upright objects. Small objects as cards and timepieces are instinctively held normal to the rays of the nearest lamp. The vertical component of street illumination should have due consideration for its importance in revealing the architecture of buildings and assisting in the recognition of persons.

TYPES OF ILLUMINANTS. — The illuminants most extensively used in street lighting are as follows: (*For detailed descriptions and data see Lamps, Arc; Lamps, Incandescent; and Gas Lighting.*)

Electric Arc Lamps on Series Circuits, including (*a*) carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types, with standard currents of 6.6,

7.5 and 9.6 amperes; (*b*) flame carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types, with standard currents of 6.6, 7.5 and 9.6 amperes; and (*c*) metallic or luminous arcs of open d-c. type with standard currents 4.0, 5.5 and 6.6 amperes, arranged for suspension and pedestal mounting.

Electric Arc Lamps on Multiple Circuits at or near 110 volts, including (*a*) carbon arcs of open d-c., enclosed d-c. and enclosed a-c. types; (*b*) flame carbon of open d-c., enclosed d-c. and enclosed a-c. types; and (*c*) quartz tube mercury arcs.

Electric Incandescent Lamps, Series Type, including (*a*) vacuum lamps with standard currents of 3.5, 4.0, 5.5, 6.6. and 7.5 amperes and range of candle-power from 32 to 350; and (*b*) gas-filled lamps of from 57 to 500 watts, and from 80 to 1000 candle-power.

Electric Incandescent Lamps, Multiple Type at or near 110 volts of from 25 to 1000 watts and from 21.5 to 1670 candle-power.

High-pressure Gas Lamps of upright and inverted types, including (*a*) compressed gas, (*b*) compressed air and (*c*) compressed gas and air types.

Low-pressure Gas Lamps of upright and inverted types, including (*a*) single mantle lamps and (*b*) clusters of 3, 4 and 5 mantles.

Naphtha Vapor Mantle Lamps of self-contained, upright type with nominal candle-power of from 45 to 60.

Relative Advantages of Various Street Illuminants. — The advantages of electric lighting over gas lighting are (1) superior flexibility in sizes and possible locations, (2) greater ease of maintenance, (3) availability of white color, and (4) ease of control from central points with series circuits. The advantages of gas over electricity are (1) lower probability of interruption by accident, (2) steadiness of light and (3) the low intrinsic brilliancy of mantles.

Both electric and gas lamps suffer fluctuations due to unsteady pressure, but these conditions are more easily regulated in electric systems. Skillful maintenance is necessary to insure the proper efficiency of all street lamps, but affords a simpler problem in the case of electric lamps. High-pressure gas lamps require maintenance of an exceptionally high order.

Gas lamps are usually lighted by hand or by local automatic clock devices, though a few methods of central control have been devised. Naphtha vapor lamps are difficult to maintain in good efficiency and require costly attention, as each lamp must be filled by hand and heated by a blast torch before lighting. Such lamps should be used only where electric or gas lighting from central systems is not available.

Series electric lamps tend to economy in power distribution and to simplicity of central control. Separate mains must be used for all circuits requiring central control. Lamps operated in multiple from regular mains are lighted and extinguished by hand or by special clock switches. The high voltage of series circuits involves elements of danger and liabilities to interruption by accidents not found in parallel systems. Parallel systems can employ metal poles and grounded supports with greater safety. Incandescent electric lamps provide a very wide range of candle-power and involve smaller expense for maintenance and renewals than arc or gas lamps. On well-regulated circuits incandescent lamps surpass all other street illuminants in steadiness. The effectiveness of incandescent lamps as commonly installed without diffusing shades is often badly impaired by glare.

The color of light is relatively less important in street lighting than in interiors. White is generally preferred, as satisfying a sense of naturalness. Yellow and green have superior penetrating power in fog and smoke.

Small vs. Large Units. — Large units are generally more efficient than small units and involve relatively less expense for installation, maintenance

and operation per unit of light production. With proper spacing the light of small units can be more completely utilized on roadways and produces a more uniform illumination. Small units lend themselves more readily to decorative schemes and to the lighting of shady streets and curving roadways. The effect of numerous small units at low levels, especially when unshaded, is distinctly more obtrusive and glaring than a small number of high power sources hung fairly high and well diffused.

Ratings of Street Lamps.—Street lamps are variously rated in candle-power, watts and rate of gas consumption. Much confusion is caused by loose usage of the term candle-power, which in different cases refers to mean horizontal, maximum, mean spherical, mean lower hemispherical and merely nominal values. Horizontal and maximum candle-power or that at any specified angle are significant only when comparing lamps having a definite form of light distribution in common. Mean spherical candle-power gives the gross light output of a lamp without any index to the effectiveness with which it may be utilized. It is an appropriate rating for a bare luminous element without accessories. The mean lower hemispherical candle-power is perhaps the best single index to the available light output of a lamp, but it cannot be conveniently measured in service. Candle-power ratings are sometimes of a purely nominal nature, e.g., the 1200 and 2000 candle-power ratings applied to carbon arc lamps denote lamps consuming 330 and 480 watts respectively.

The rated candle-power of gas and gasoline mantle lamps usually represents the maximum intensity which a given type of lamp can produce commercially. This rating almost invariably exceeds the average results in service by a wide margin due to imperfect maintenance, and can serve only as an index to the type of lamp referred to.

Incandescent electric lamps are rated in horizontal candle-power on the basis of actual initial performance. The candle-power rating of incandescent lamps installed on streets with reflectors is often taken to imply the actual average intensity at some angle between 15° and 25° below horizontal. A test of 130 incandescent lamps with flat enameled metal reflectors in service, which was made by the writer in 1913, showed the average candle-power of such units at 25° below horizontal to be 111.6 per cent of the rated horizontal candle-power of the lamps.

Indefinite candle-power specifications in lighting contracts have caused much litigation. Arc lamps of all types are preferably rated in watts, as affording the only accurately measurable index to their performance. The specification that a reasonable average of candle-power as indicated by a prescribed photometric test shall be maintained is recognized as a valuable check on the quality of maintenance and service.

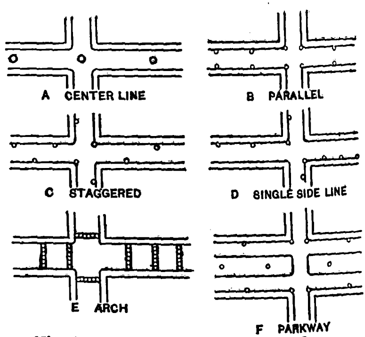

Fig. 1. Spacing Schemes for Street Lamps

SPACING OF LAMPS.—The plans of lamp spacing most widely used are shown diagrammatically in Fig. 1. Plan A, or single center line spacing, is the most effective method of using high-power units. Lamps may be hung from span wires between poles or buildings or from mast arms projecting over roadways. In some cases lamps

are mounted directly on poles or standards in a central parkway or series of safety isles. Center suspension is especially desirable when only one lamp is placed at an intersection. Plan B, or parallel spacing, and Plan C, or staggered spacing, are best adapted to the brilliant lighting of main thoroughfares with high-power units and the lighting of ordinary streets with small units. The staggered arrangement favors the meeting of a definite minimum requirement of roadway illumination with the smallest number of lamps per mile. Plan D, or single side line spacing, sacrifices symmetry and uniformity to the convenience of running electric circuits or gas piping on but one side of the street. Plan E, or arch lighting, is adapted only to incandescent electric lamps; it tends to give a street a festive appearance, but is not an effective method of illumination. Plan F, or parkway lighting, is of obvious value where the roadway is divided as shown.

Side vs. Center Mounting. — Fig. 2 shows the effect of center and side mounting on the per cent of the total light which falls within the limits of streets

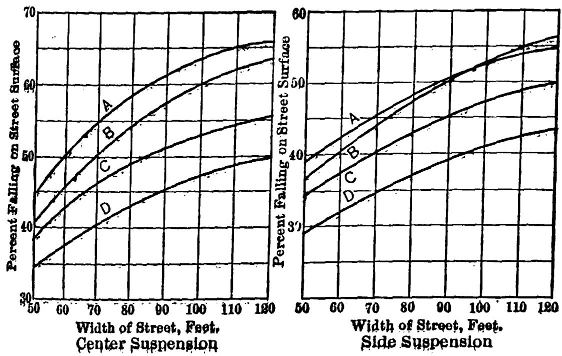

Fig. 2. Per Cent of Light from Arc Lamps which falls within Limits of the Street

A. 9.6 amp. Open Carbon Arc, Clear Globe
B. 4 amp. Magnetite Arc, Clear Globe
C. 6.6 amp. Magnetite Arc, Opal Globe
D. 6.6 amp. Enclosed Carbon Arc, Opal Globe

of various widths. These curves all refer to a mounting height of 20 feet above street level. The lamps with side mounting are assumed to be over a curb line which is distant from the nearer street line by an amount equal to one-fifth the total width of the street. The higher efficiency of center mounting is apparent. (*Data by P. S. Millar, Trans. Ill. Eng. Soc., Vol. 5, p. 658.*)

Various attempts have been made to increase the percentage of light thrown on the street by reflectors of special design which deflect lengthwise of the street light which would otherwise be thrown to the sides. These have had a very limited acceptance.

Excellent use of large units at intersections and small units at intermediate points may be made on secondary streets, especially where foliage interferes with the distribution of light at distances. On curved roadways it is preferable to locate the lamps on the outer sides of the curves, as they are then visible at greater distances.

Height of Suspension. — The spacing of lamps should be laid out with due regard to the height of suspension of the lamps and the degree of minimum illumination to be provided. In many cities a standard height of mounting is em-

ployed with each type of lamp. When such is the case, spacing problems are readily solved by the aid of diagrams such as shown in Fig. 3. Taking account of the suspension height and the light distribution curve of each lamp in its normal service condition, the horizontal distances from the axis of the lamp at

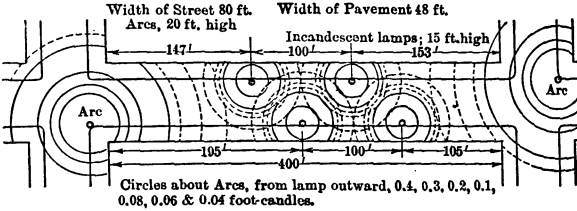

Fig. 3. Spacing and Illumination Plan for a Minimum Normal Illumination of 0.04 Foot-candle

which various normal intensities of illumination are produced at an appropriate level, as that of the street or at a height four feet above the street, are computed by the point-by-point method. Using these distances as radii, circles are drawn to scale about a center representing the axis of the lamp and are marked with the corresponding intensity of illumination. These diagrams are preferably made on translucent tracing cloth and several of each type should be prepared. A plan of the space to be lighted is drawn to the same scale on a separate paper and the circle diagrams are used as templates for various trial spacings until the desired result is obtained. The circles then furnish points for the plotting of illumination profiles or contours at the center line and curb lines, from which the approximate average illumination is readily computed. The illustration shows an appropriate location for 4-ampere magnetite arcs, with globes at street intersections, and 60-candle-power series incandescent lamps with flat enameled metal reflectors at intermediate points, to produce a minimum normal illumination of 0.04 f.c. on a section of street 80 feet wide and 480 feet long lying between centers of intersecting streets.

Selection of Height of Suspension. — The most appropriate suspension height for a street lamp depends on its light output, form of distribution and intrinsic brilliancy, and upon the degree of minimum illumination required. It is practically impossible to realize uniform illumination from large arcs and high-pressure gas lamps without higher suspension than that commonly employed. The usual result is a bright spot immediately about the lamp and low illumination at mid-points. The contrast so produced reduces the effectiveness of the light.

A high ratio of suspension height to horizontal spacing tends to improve the uniformity of light distribution and to increase the distance over which a single lamp can provide illumination above a specified minimum value. A high ratio of height to distance is especially desirable when the maximum light intensity of the lamp is more than 30° below the horizontal.

The following example may be taken. In Fig. 4 polar curve (*a*) refers to a 510-watt magnetite arc with clear globe and (*b*) to a 450-watt d-c. flame arc with vertical electrodes and a light opal globe. The illumination curves show the normal illumination at various distances for various suspension heights. In case (*a*) the maximum intensity is but 10° below the horizontal and little gain at distant points is obtained by employing a suspension height exceeding 25 feet. In case (*b*), however, the maximum intensity is much lower on the polar curve and a much higher suspension could advantageously be employed. Fig. 5 shows

the effect of height of suspension of these two lamps on the normal illumination at various distances.

The actual suspension height is often determined by the exigencies of trimming, by the length of wooden poles available, and by the necessity of distributing light below the foliage of trees. It must be recognized that a lamp with high mounting throws a smaller total percentage of its light

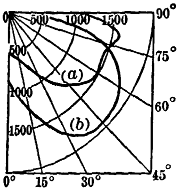

Fig. 4. Polar Light Distribution Curves of (a) 6.6-ampere Magnetite Arc with Clear Globe and (b) 450-watt Enclosed Flame Arc

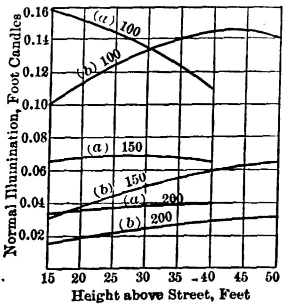

Numbers on curves are horizontal distances (feet) from source

Fig. 5. Effect of Height of Suspension of Arc Lamps of Fig. 4 on Normal Illumination at Various Distances

on the street, and that the gain is from the better distribution to distant points.

LIGHTING SCHEDULES. — All-night schedules provide for a yearly total of from 3830 to 4000 hours of operation. The former total results from lighting 30 minutes after sunset and extinguishing an hour before sunrise. The latter involves one half-hour longer burning each night. The "Philadelphia moonlight schedule" allows lamps to remain unlighted on nights when the moon is full or nearly so and on other nights the lamps are lighted one hour before moonset and extinguished one hour after moonrise. This schedule calls for an annual total of 2000 hours of operation. The "Frund system" ignores the moon until midnight, after which the provisions of the moonlight schedule apply, making an annual total of 3000 hours. As a large portion of the cost of street lighting is due to fixed charges the saving of reduced schedules as compared with an all-night schedule is much less in proportion than the reduction of hours. Each year the *Electrical World* issues a detailed set of lighting schedules for the ensuing year, separate tables being furnished for northern, middle and southern latitudes of the United States.

COST OF STREET LIGHTING. — The cost of street lighting is usually based on an annual price per lamp or fixture for a specified number of hours of burning. This cost may properly include all fixed charges on the lamps and their accessories as well as a due proportion of the charges on poles, lines, transformers and other appliances assignable to the service, all costs of maintenance and renewals involved in the service, and a reasonable charge for the energy supplied. These costs naturally vary with the character of the distributing system, value of poles, rate of depreciation of lamps and the cost of producing electrical energy. Depreciation rates on street lamps and special appliances used in supplying them are apt to reach or exceed 10 per cent, due to rapid obsolescence. The average prices charged per year for various types of street lamps operated on all-night schedules in a representative group of cities are given below:

PRICES PER YEAR FOR ELECTRIC STREET LAMPS; ALL-NIGHT SCHEDULE

Type of lamp	Cities averaged	Average rate	Maximum rate	Minimum rate
4-amp. magnetite arc.	27	$63.00	$80.00	$45.00
6.6-amp. enc. carbon arc.........	40	73.00	100.00	74.00
7.5-amp. enc. a-c. carbon arc....	16	70.00	85.00	60.00
80-c.p. series tungsten lamp......	6	29.50	39.00	18.50
60-c.p. series tungsten lamp......	16	23.25	28.00	15.00
40-c.p. series tungsten lamp......	4	20.00	28.00	18.50
32-c.p. series tungsten lamp	16	18.00	22.50	12.50

Single-mantle gas lamps are usually furnished on an all-night schedule for prices ranging from $20 to $25 per annum. In many of the smaller cities special display systems of incandescent electric lamps are operated on main business streets, the expense being assumed jointly by the city and the occupants of abutting property. The lamps are usually arranged in arches, festoons or in clusters on pedestals, and are often operated from constant-potential mains to permit the turning off of part of the lamps after midnight. These systems are usually maintained by the operating company and charged for on a flat rate basis.

INDETERMINATE FORMS. — (*See also Derivatives.*) Let $f(x)$ and $F(x)$ be any two functions of x and let $y = \frac{f(x)}{F(x)}$. For certain values of x, both $f(x)$ and $F(x)$ may be zero, making y equal to $\frac{0}{0}$, an expression which, considered alone, may be anything between 0 and ∞. Its true value may, however, be determined from the nature of the functions $f(x)$ and $F(x)$ by the following process, which involves finding the derivatives of the two functions. If $y_1 = \frac{0}{0}$ when $x = x_1$, then

$$y_1 = \left.\frac{\frac{d}{dx}f(x)}{\frac{d}{dx}F(x)}\right|_{x=x_1}$$

which expression may have a perfectly determinate value. For example if

$$y = \frac{x^2 - 4}{x^3 - 8}$$

and $x = 2$, then

$$y_1 = \frac{0}{0} = \left.\frac{2x}{3x^2}\right|_{x_1=2} = \frac{4}{12} = \frac{1}{3}.$$

If the ratio of the derivatives is still indeterminate, differentiate numerator and denominator again and, if necessary, repeat the process until a determinate form is obtained.

When $y = \frac{f(x)}{F(x)}$ reduces to the indeterminate form $\frac{\infty}{\infty}$ for any particular value x_1 of x, the corresponding value of y is

$$y_1 = \left.\frac{\frac{d}{dx}\left(\frac{1}{F(x)}\right)}{\frac{d}{dx}\left(\frac{1}{f(x)}\right)}\right|_{x=x_1}$$

When $y = f(x) \times F(x)$ reduces to the indeterminate form $0 \times \infty$ for any particular value x_1 of x, the corresponding value of y is

$$y_1 = \left.\frac{\frac{d}{dx}f(x)}{\frac{d}{dx}\left(\frac{1}{F(x)}\right)}\right|_{x=x_1}$$

[W. A. Del Mar.]

INDUCTANCE AND INDUCTIVE REACTANCE. — (*See also Alternating Currents; Electricity and Magnetism, Principles of; Skin Effect; Transmission Lines.*) The phenomena of self and mutual inductance are described in the article on *Electricity and Magnetism, Principles of*. In general, when the current i_1 in a circuit, No. 1 say, is varying at the rate $\frac{di_1}{dt}$, a potential drop, in the direction of the current (or *back* e.m.f.) is induced in the circuit, which may be written

$$v_{11} = L_1 \frac{di_1}{dt},$$

where L_1 is called the coefficient of self induction, or self inductance, or simply the inductance, of the circuit. Similarly, when a second circuit, No. 2 say, is in the vicinity of No. 1 and the current i_2 in No. 2,* is varying at the rate $\frac{di_2}{dt}$, an additional potential drop is induced in circuit No. 1 equal to

$$v_{12} = M_{12} \frac{di_2}{dt},$$

where M_{12} is called the coefficient of mutual induction, or simply the mutual inductance, of one circuit with respect to the other.

When the currents in both instances are sine-wave currents of effective values I_1 and I_2 respectively and of frequency f, the effective values of these potential drops are

$$V_{11} = x_1 I_1 \qquad \text{and} \qquad V_{12} = x_{12} I_2 \tag{1}$$

and V_{11} leads I_1 by 90 degrees, and V_{12} leads i_2 by 90 degrees, and

$$x_1 = 2\pi f L_1 \qquad \text{and} \qquad x_{12} = 2\pi f M_{12}. \tag{1a}$$

x_1 is called the inductive self-reactance, or simply the inductive reactance of circuit No. 1. (*see Alternating Currents*), and x_{12} is called the inductive mutual reactance of one circuit with respect to the other. The mutual inductance, and therefore the mutual reactance, between any two circuits is the same for No. 1 with respect to No. 2 as for No. 2 with respect to No. 1, i.e., $M_{12} = M_{21}$ and $x_{12} = x_{21}$.

The total inductive† drop in any circuit due to the *variation of the current* in this and in any number of neighboring circuits is

$$v_1 = L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + \mathrm{M}_{13} \frac{di_3}{dt} + \text{etc.} \tag{2}$$

For sine-wave currents of frequency f the total inductive* drop is, in *vector notation* (*see Alternating Currents*),

$$V_1 = j\,(x_1 I_1 + x_{12} I_2 + x_{13} I_3 + \ldots). \tag{2a}$$

Units of Inductance and Reactance. — The practical unit of inductance is the henry, the c.g.s. electromagnetic unit the abhenry (also called a "centimeter"), and the c.g.s. electrostatic unit the stathenry. Inductances are fre-

* i_2 is to be considered positive with respect to i_1 when the flux lines threading No 1 due to the current in No. 2 thread through No. 1 in the same direction as the flux lines due to the current in No. 1.

† In addition to these drops there are also the resistance drop and such other back e.m f.'s as may be present. See *Alternating Currents*.

quently expressed in thousandths of a henry, i.e., in millihenrys. The units of reactance are the same as the units of resistance (q.v.) See *Units and Conversion Factors* for the interrelations of the various units.

Total Inductance of Two or More Circuits in Series. — When several circuits, having the coefficients L_1, L_2, L_3, etc., and M_{12}, M_{13}, M_{23}, etc., are connected in series the currents $i_1 = i_2 = i_3 = \text{etc.} = i$, say, and the total induced e.m.f. is $v = v_1 + v_2 + v_3$, etc., or

$$v = \left[(L_1 + L_2 + L_3 + \text{etc.}) + 2\,(M_{12} + M_{13} + M_{23} + \text{etc.})\right]\frac{di}{dt},$$

whence the resultant or total inductance is

$$L = (L_1 + L_2 + L_3 + \text{etc}) + 2\,(M_{12} + M_{13} + M_{23} + \text{etc.}). \tag{3}$$

This relation makes possible the accurate calculation of the self inductance of a coil of a number of turns when the self inductance of each turn and the mutual inductance of each pair of turns are known.

RELATION BETWEEN FLUX, CURRENT AND INDUCTANCE. — When the permeability of the conductors and of the medium between and surrounding them is constant (e.g., when the conductors and medium are non-magnetic substances), the self and mutual inductances are constants, independent of the values of the currents, for any given arrangement, shape and size of the circuits. Under these conditions the total number of linkages (*see Electricity and Magnetism, Principles of*) between the flux lines linking any particular circuit, No. 1, and the turns forming that circuit may be expressed by the relation

$$\lambda_1 = L_1 i_1 + M_{12} i_2 + M_{13} i_3 + \text{etc.}, \tag{4}$$

where

$L_1 i_1 = \lambda_{11} =$ the linkages between the flux lines due to the current i_1 in circuit No. 1 and the turns of circuit No. 1,

$M_{12} i_2 = \lambda_{12} =$ the linkages between the flux lines due to the current i_2 in circuit No. 2 and the turns of circuit No. 1, etc.

Hence the common definition of inductance as "linkages per unit current." In certain simple cases the linkages per unit current may be calculated from the configuration of the circuit or circuits, starting from the fundamental relations given by equations (35), (36) and (29) in the article on *Electricity and Magnetism, Principles of.*

Internal Flux, Internal Inductance and Internal Reactance. — In the case of a wire of finite cross-section the various "filaments" of which the wire may be considered as made up are not all linked by the same number of flux lines, and consequently the back e.m.f.'s induced in the various filaments are different, tending to produce a non-uniform distribution of current. This variation in the induced e.m.f. from filament to filament is due only to that portion of the total flux which actually cuts the wire in question; it may therefore be called the "internal flux," and that portion of the inductance or reactance corresponding to this internal flux may be designated as the "internal inductance" and "internal reactance" respectively. Although the internal flux tends to produce a non-uniformity in the distribution of current, this effect is counteracted by the resistance of the wire and for ordinary non-magnetic wires at frequencies under 60 cycles per second the current remains practically uniformly distributed over the cross-section of the wire. See article on *Skin Effect.*

FORMULAS FOR SELF INDUCTANCE. — The following formulas are taken from a very comprehensive paper on the calculation of inductance

by Rosa and Grover in the *Bull. Bur. Stand.*, Vol. 8, No. 1, p. 1, 1912, in which the accuracy of the various formulas is thoroughly discussed and many others given, as well as tables to minimize the labor of calculation.

Unless otherwise stated *all formulas are in c.g.s. electromagnetic units;* the conversion factors are given in the article on *Units and Conversion Factors.*

Self Inductance of a Single Circular Turn formed by a Wire of Circular Cross-Section. — Let a = mean radius of the turn, in centimeters, r = radius of the wire, in centimeters; then the self inductance is

$$L = 4\pi a\left[\left(1+\frac{r^2}{8a^2}\right)\log_e\frac{8a}{r}+\frac{r^2}{24a^2}-1.75\right]. \qquad (5)$$

This formula is derived from an infinite series in $\frac{r}{a}$, hence for $\frac{r}{a}$ large it is approximate only; however, for $\frac{r}{a}$ less than 0.1 which covers all ordinary cases, the error is less than 1 part in 100,000.

Mutual Inductance of Two Co-axial Circles. — Dimensions as in Fig. 1, all in centimeters. Put

$$k=\sqrt{1-\left(\frac{m_2}{m_1}\right)^2}, \qquad k_1=\frac{m_1-m_2}{m_1+m_2}.$$

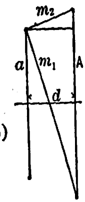

Fig. 1.

For $k < 0.2$ use the formula

$$M=\frac{\pi^2k^3}{4}\sqrt{Aa}\left[1+\frac{3}{4}k^2+\frac{75}{128}k^4+\frac{245}{512}k^6+\ldots\right], \qquad (6)$$

the general term in the brackets being

$$\left(\frac{3\cdot5\cdot7\ldots(2n+1)}{4\cdot6\cdot8\ldots(2n+2)}\right)^2\frac{(2n+2)}{(2n-1)}k^{2n}.$$

For $k > 0.2$ use the formula

$$M=2\pi^2k_1^{3/2}\sqrt{Aa}\left[1+\frac{3}{8}k_1^2+\frac{15}{64}k_1^4+\frac{175}{1024}k_1^6+\ldots\right], \qquad (6a)$$

the general term in the brackets being

$$\left(\frac{n+1}{2n+1}\right)\left[\frac{3\cdot5\cdot7\ldots(2n+1)}{4\cdot6\cdot8\ldots(2n+2)}\right]^2k^{2n}.$$

Self Inductance of a Long Solenoid* of Circular Cross-Section. — Let

l = axial length of solenoid in centimeters,
n_1 = number of turns per centimeter length, i.e., total number of turns = n_1l,
a = mean radius of the solenoid in centimeters

Then for $\frac{a}{l}$ small, the self inductance is, to a first approximation,

$$L=4\pi^2n_1^2a^2l. \qquad (7)$$

There is a considerable error in this formula, due to the end effect, but the variations in L due to changes in l are almost exactly proportional to the changes in

* By a solenoid is meant a coil in which the wire forms a uniform, straight, cylindrical helix.

l, and hence this formula may be used for calculating the corresponding variations in L as long as $\frac{a}{l}$ remains small.

Self Inductance of a Single-layer Short Solenoid of Circular Cross-Section. — For such a solenoid (see Fig. 2) the summation formula, equation (3), becomes when there are n turns,

$$L = nL_1 + 2(n-1)M_{12} + 2(n-2)M_{13} + 2(n-3)M_{14} + \ldots + 2M_{1n}, \tag{8}$$

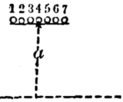

Fig. 2.

where L_1 is the self inductance of a single turn, M_{12} is the mutual inductance of the first and second turns or any two adjacent turns, M_{13} is the mutual inductance of the first and third or of any two turns separated by one, etc., and M_{1n} is the mutual inductance of the first and last turns. L_1 may be calculated from equation (5) and the M's from equation (6) or (6a). The general equation (3) may also be used to calculate the self inductance of a coil of any number of layers, but the calculation becomes tedious.

Self Inductance of Circular Coil of Rectangular Section (Fig. 3). — Dimensions as in Fig. 3, all in centimeters, also

N = total number of turns,
$R = 0.2235\,(b + c)$.

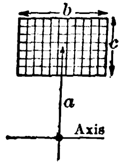

Fig. 3.

Then to a degree of approximation sufficient for most practical purposes

$$L = 4\pi a N^2 \left\{ \log_e \frac{8a}{R}\left(1 + \frac{3R^2}{16a^2}\right) - \left(2 + \frac{R^2}{16a^2}\right)\right\}. \tag{9}$$

Mutual Inductance of Two Concentric Co-axial Solenoids.* — All dimensions being in centimeters, let

l = one-half the length of the *shorter* coil,
x = one-half the length of the *longer* coil,
A = radius of *outer* coil (which may be either the shorter or longer coil),
a = radius of the *inner* coil,

$$d = x\sqrt{1 + \left(\frac{A}{x}\right)^2},$$

N_1 and N_2 = the *total* number of turns in the first and second coils respectively.

Then as a first approximation, for $\frac{A}{x}$ small, the mutual inductance between the two coils is

$$M = \frac{2\pi^2 a^2 N_1 N_2}{d}. \tag{10}$$

By calculating a sufficient number of terms the mutual inductance may be obtained exactly from the formula

$$M = \frac{2\pi^2 a^2 N_1 N_2}{d}\left[1 - \frac{A^2}{2d^4}\,\frac{4l^2 - 3a^2}{4} - \frac{A^2(4x^2 - 3A^2)}{8d^8}\cdot\frac{8l^4 - 20l^2a^2 + 5a^4}{8} - \frac{A^2(8x^4 - 20x^2A^2 + 5A^4)}{16d^{12}}\cdot\frac{(64l^6 - 336l^4a^2 + 280l^2a^4 - 35a^6)}{64} - \ldots\right]. \tag{10a}$$

* One solenoid inside the other with their centers coinciding.

Mutual Induction of Two Co-axial Circular Coils Each of Rectangular Section (Fig. 4). — Dimensions as in Fig. 4, all in centimeters. N_1 and N_2 represent the total number of turns on the two coils respectively. The following formula, known as the "formula of quadratures," is sufficiently exact for most practical cases:

$$M = \frac{N_1 N_2}{6}(M_1 + M_2 + M_3 + M_4 + M_5 + M_6 + M_7 + M_8 - 2M_0), \tag{11}$$

where M_0 is the mutual inductance of the two central turns o_1 and o_2 in Fig. 4. M_1 is the mutual inductance of the circle through o_2 and the circle through 1, M_5 is the mutual inductance of the circle through o_1 and the circle through 5, etc. These mutual inductances M_0, M_1 . . . M_8 may be calculated from equation (6) or (6a). When the sections of the two coils are small compared with their distance apart, $M_0 = M_1 = \ldots M_8$ and equation (11) becomes

$$M = N_1 N_2 M_0. \tag{11a}$$

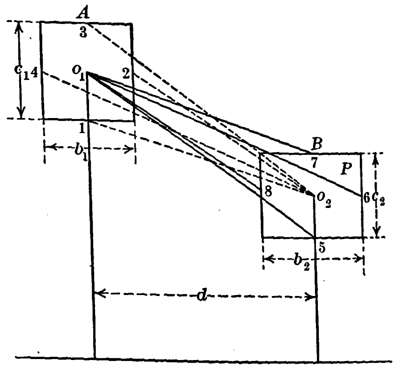

Fig. 4.

INDUCTANCE OF STRAIGHT CONDUCTORS. — The inductance of a circuit formed by straight conductors, such as the wires of a transmission line, may be considered from two points of view, viz., (1) each conductor may be looked upon as having a certain *self* inductance independent of the position of the other conductors forming the circuit or circuits and a *mutual* inductance with each of these conductors or (2) when the conductors are symmetrically arranged and the currents in them bear a fixed relation to one-another, as in a two-wire single-phase or symmetrical three-wire three-phase transmission line, each conductor may be looked upon as having a *total* inductance which takes into account both its self inductance and its mutual inductance with respect to the other wires. In the case of a 2-wire line the total inductance of the loop formed by the two conductors is twice the total inductance of *each* conductor; in the case of more than two wires the "loop inductance" has no simple physical meaning.

In the following paragraphs are given the formulas for *self*, *mutual* and *total* inductance *per conductor* for straight conductors of various sections and for various arrangements of such conductors. *The formulas are all in c.g.s. electromagnetic units* unless otherwise specified; see *Units and Conversion Factors.*

Self Inductance of a Single Straight Round Wire, Return Neglected. — Let

l = length of wire, in centimeters,
d = diameter of round wire, in centimeters,
$r = \frac{d}{2}$ = radius of round wire, in centimeters.

Then for a round wire the self inductance is

$$L' = 2\left[l \log_e \frac{l + \sqrt{l^2 + r^2}}{r} - \sqrt{l^2 + r^2} + \frac{l}{4} + r\right] \tag{12}$$

$$= 2l\left[\log_\epsilon \frac{2l}{r} - \frac{3}{4}\right] \text{ approximately.} \qquad (12a)$$

Where the permeability of the wire is μ, and that of the medium outside is unity and the frequency low (12a) appears in the form

$$L' = 2l\left[\log_\epsilon \frac{2l}{r} - 1 + \frac{\mu}{4}\right]. \qquad (12b)$$

This last formula is of theoretical interest only, as the value to assign to μ is doubtful and when such wires are used even for currents of moderate frequencies, the skin effect is appreciable; see article on *Skin Effect*.

External and Internal Self Inductance of a Round Wire. — The self inductance of a round wire may be considered as made up of two parts, viz., the inductance due to the flux *external* to the wire and that due to the flux *within* the wire. The first or "external" inductance is

$$L_e = 2l\left[\log_\epsilon \frac{2l}{r} - 1\right], \qquad (13)$$

and the "internal" self inductance is

$$L_i = l\frac{\mu}{2}. \qquad (13a)$$

Self Inductance of a Hollow Tube of Circular Section, Return Neglected. — The *external* inductance is the same as for a solid wire, i.e., equation (13), taking for r the external radius of the tube. The *internal* inductance of the tube, putting r_2 = external radius and r_1 = internal radius, is

$$L_i = 2\mu l\left[\frac{r_1^4}{(r_2^2 - r_1^2)^2}\log_\epsilon \frac{r_2}{r_1} - \frac{1}{4}\,\frac{3r_1^2 - r_2^2}{r_2^2 - r_1^2}\right]. \qquad (14)$$

The term in the square brackets is always less than ¼, i.e., the internal inductance of a hollow tube is always less than the internal inductance of a solid wire; see equation (13a). In the limit, where $r_1 = r_2$ (tube with infinitely thin walls), the *internal* inductance is zero.

Self Inductance of a Straight Bar or Strip, Return Neglected. — For a straight bar of a non-magnetic substance and of rectangular cross-section the self inductance, neglecting the return circuit, is

$$L' = 2l\left[\log_\epsilon \frac{2l}{a+b} + \frac{1}{2} + \frac{0.2235\,(a+b)}{l}\right], \qquad (15)$$

where a and b are the lengths of the two edges, in centimeters.

Mutual Inductance of Two Parallel Straight Wires or Bars. — See Fig. 5. Same notation as above and in addition let

D = distance between centers of the two wires, in centimeters.

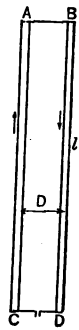

Fig. 5.

Then the mutual inductance between the two is

$$M = 2\left[l\log_\epsilon \frac{l + \sqrt{l^2 + D^2}}{D} - \sqrt{l^2 + D^2} + D\right] \qquad (16)$$

$$= 2l\left[\log_\epsilon \frac{2l}{D} - 1 + \frac{D}{l}\right] \text{approximately,} \qquad (16a)$$

when the length l is great in comparison with D.

Equation (16), which is an exact expression when the wires have no appreciable cross-section, is not an exact expression for the mutual inductance of two parallel cylindrical wires, but is not appreciably in error even when the section is large and D is small if l is great compared with D.

Equation (16) is also applicable, with a practically negligible error to bars of rectangular section and in fact to the mutual inductance between any two parallel conductors of any section and external to each other, e.g., between an overhead wire and a rail, the distance D being the distance* between the center of gravity of the two sections.

Mutual Inductance Between a Tube and an Interior Wire. — Using the same notation as for equation (14) above the mutual inductance in this case is

$$M = 2l\left[\log_\epsilon 2l - \frac{r_2^2 \log_\epsilon r_2 - r_1^2 \log_\epsilon r_1}{r_2^2 - r_1^2} - \frac{1}{2}\right]. \qquad (16b)$$

Total Inductance of a Two-wire Transmission Line. — Let the two wires (Fig. 5) be designated as No. 1 and No. 2 and the currents as i_1 and i_2. Since $i_2 = -i_1$, from equation (2) the total inductive drop in each wire is

$$v_1 = (L_1 - M_{12})\frac{di_1}{dt}.$$

The total inductance of each wire is then $L = L_1 - M_{12}$, where L_1 is given by equation (12) or (14) and M_{12} by equation (16). For a length so great that d and D are negligible compared with l, this total inductance per wire for equal round wires becomes

$$L = 2l\left[\log_\epsilon \frac{2D}{d} + \frac{\mu}{4}\right],$$

where d is the diameter of each wire. The total inductance of the line per unit length of *wire*† is

$$\left.\begin{aligned} L &= \frac{\mu}{2} + 2\log_\epsilon \frac{2D}{d} && \text{abhenries per centimeter} \\ &= 0.01524\mu + 0.14037 \log_{10}\frac{2D}{d} && \text{millihenries per 1000 feet} \\ &= 0.08047\mu + 0.74113 \log_{10}\frac{2D}{d} && \text{millihenries per mile,} \end{aligned}\right\} \qquad (17)$$

where D and d may be expressed in any units of length provided they are both expressed in the *same* units. The formulas given in equation (17) also apply approximately to stranded wires, provided d is taken as the diameter of the solid wire having a cross-section equal to that of the copper in the stranded wire, i.e., the inductance of a No. 0000 stranded wire on a given spacing is approximately the same as that of a No. 0000 solid wire on the same spacing.

Tables of L and the corresponding reactances for 25 and 60 cycles for various sizes of wires and various spacings are given below.

Total Inductance of a Rectangle. — Let L_a = self inductance of long side, L_b = self inductance of short side (calculated from the proper formulas, 12 to 15) and let M_a = mutual inductance between the two long sides and M_b = the mutual inductance between the two short sides (calculated from formula 16); then the total inductance of the rectangle is

$$L = 2(L_a - M_a) + 2(L_b - M_b)$$

* Accurately, the geometrical mean distance between the two areas; see *Bull. Bur. Stand.*, 1912, Vol. 8, pp. 125 and 166. For round wires, solid or tubular, the geometrical mean distance between them is exactly the distance between their centers.

† To obtain the total inductance of both wires multiply by *twice* the length of the line.

SELF INDUCTANCE OF SOLID NON-MAGNETIC WIRES*

Millihenries per 1000 FEET of each wire of a single-phase or of a symmetrical three-phase line

Size of wire, cir. mils. or A.W.G.	Diam. of wire, inches	Inches between wires, center to center

* The reactances given in this table also apply, with a practically negligible error, to ordinary stranded wires of the *same cross-section.*

Total Self Inductance of a Concentric Main. — In a similar manner the total inductance of a concentric main may be found from equations (3), (13), (14) and (16b), which give for the total inductance per unit length of *cable*

$$L = 2\left[\log_\epsilon \frac{d_2}{d_1} + \frac{d_3^4}{(d_3^2 - d_2^2)^2}\log_\epsilon \frac{d_3}{d_2} - \frac{d_3^2}{2\,(d_3^2 - d_2^2)}\right] \text{ abhenries per centimter,}$$

where d_1 = diameter of internal conductor, assumed solid, d_2 = internal diameter of outer conductor and d_3 = external diameter of outer conductor.

Inductive Drop in a Three-wire Transmission Line. — Let the wires be designated as Nos. 1, 2, and 3; and the three currents in the direction away from the generator as i_1, i_2 and i_3. From equation (1) the inductive drop in each wire* is

$$\left.\begin{aligned} v_1 &= L_1\frac{di_1}{dt} + M_{12}\frac{di_2}{dt} + M_{13}\frac{di_3}{dt},\\ v_2 &= M_{12}\frac{di_1}{dt} + L_2\frac{di_2}{dt} + M_{23}\frac{di_3}{dt},\\ v_3 &= M_{13}\frac{di_1}{dt} + M_{23}\frac{di_2}{dt} + L_3\frac{di_3}{dt}.\end{aligned}\right\} \qquad (18)$$

The values of the L's and M's in terms of the radii and distances apart of the three wires are given in equations (12) or (14) and (16).

Equilateral Triangle Arrangement. — For ordinary three-phase work when there is no neutral current, the sum of the three line currents at any instant is equal to zero, whence

$$(i_2 + i_3) = -i_1,\ (i_1 + i_3) = -i_2, \text{ and } (i_1 + i_2) = -i_3.$$

When the three wires are all of the same size and are arranged so that they form the three edges of an equilateral prism, a common arrangement, $L_1 = L_2 = L_3$ and $M_{12} = M_{13} = M_{23}$, and the inductive drops per unit length in the three wires are respectively

$$v_1 = L\frac{di_1}{dt},\quad v_2 = L\frac{di_2}{dt},\quad v_3 = L\frac{di_3}{dt}, \qquad (19)$$

where L has here the same value as in equation (17), numerical values of which are given in the accompanying tables.

For a sine-wave current of effective value I and frequency f, the inductive drop in each wire per unit length of line has the effective value

$$V = 2\pi fLI \qquad (19a)$$

and leads the current in this particular wire by 90 degrees, irrespective of whether the load be balanced or not, the only condition being that no current returns to the generator through any other conductor than the three line wires.

Three Parallel Wires in the Same Plane. — Let the three wires of the three-phase system have equal diameters d, and let No. 2 be the middle wire, and let Nos. 1 and 3 be at equal distances (D between centers) from No. 2 and on opposite sides of No. 2. Under these conditions, considering unit length of line, put

L = same values as in (17), taking D as the distance between either outer and the middle wire,

and $M = 2\log_\epsilon 2 = 1.3863$ abhenries per centimeter
$= 0.04225$ millihenries per 1000 feet
$= 0.2231$ millihenries per mile.

*Note that in vector notation $\frac{di}{dt} = j\,2\pi fI$ where f is the frequency, I the current and $j = \sqrt{-1}$.

Then equations (18) for the inductive drops in the three wires become, provided only that $i_1 + i_2 + i_3 = 0$,

$$\left.\begin{aligned} v_1 &= L\frac{di_1}{dt} - M\frac{di_3}{dt}, \\ v_2 &= L\frac{di_2}{dt}, \\ v_3 &= L\frac{di_3}{dt} - M\frac{di_1}{dt}. \end{aligned}\right\} \qquad (20)$$

Such an arrangement, therefore, causes an unbalancing of the system, but when the wires are far apart, so that L is large compared with M, the effect is slight. It can be avoided by transposing the wires at intervals.

Inductance of Overhead Wires With Earth Return. — This case is not susceptible of a definite solution, since the inductance depends upon the distribution of the return current in the earth. When the current returns through one or more rails immediately below the wire, the leakage current to the earth may be neglected and the wire and rails* treated as linear conductors, applying the formulas given above. When there is no metallic return circuit, an approximate solution may be obtained by considering the earth as equivalent to the "images" of the overhead wires in the plane of the earth's surface, i.e., considering the return circuit as consisting of the same number of wires as there are overhead, these fictitious return wires being the same distance below the earth as the actual wires are above it. The value of the inductances as thus calculated can never be greater than the actual inductances but will usually be slightly less than the actual values.

EFFECT OF FREQUENCY ON INDUCTANCE. — See article on *Skin Effect.*

[H. Pender.]

*The *external* self-inductance of a rail is practically the same as that of a round wire, taking for r the perimeter of the rail divided by 2π; see equation (13). The *internal* self-inductance depends upon the permeability μ and the frequency of the current. The internal inductance, however, is small compared with the external inductance and for approximate calculations may be neglected. See *Rails, Track and Third; Trolley Systems, Overhead.*

INDUCTION COILS. — (*See also Electricity and Magnetism, Principles of; Electromagnet Windings.*) An induction coil is a device which transforms a low direct e.m.f. to a high alternating e.m.f. of unsymmetrical form. The single-winding coil, called a primary coil, is used extensively in gas-engine ignition and in automatic gas lighting, and the double-winding coil, called a secondary coil, is used for the excitation of X-ray tubes, gas-engine ignition, automatic gas lighting, electrotherapeutics and wireless telegraphy.

PRIMARY INDUCTION COIL. — The primary induction coil consists of a single coil wound upon an iron core made up of a compact bundle of soft-iron wires. To obtain a spark from such a coil it is connected in series with a battery and some kind of "make-and-break" contact. When the circuit is closed, the current increases gradually according to the expression,

$$i_t = \frac{E}{R}\left(1 - \epsilon^{-\frac{Rt}{L}}\right),$$

where i_t equals the current at any time t seconds after the circuit is closed, E equals the e.m.f. of the battery, R equals the resistance in ohms and L equals the inductance in henries of the entire circuit, and ϵ the base of the natural system of logarithms. The shape of the current curve at "make" is shown in the curve AB (Fig. 1),* which is an oscillograph record taken when an e.m.f. of 4 volts is impressed upon a primary coil of 1 ohm resistance and 0.01 henry inductance.

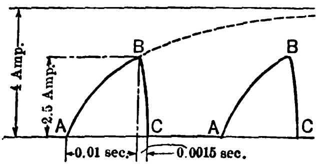

Fig. 1.

If the circuit is opened when the current reaches some value, such as B (Fig. 1), the current decreases rapidly to zero as shown in the curve BC. Since the e.m.f. induced in such a coil at any instant equals $L\frac{di}{dt}$ when the current falls from B to C, the e.m.f. induced in the coil will be many times that of the battery e.m.f. and a spark will be established between the open contacts at "break." For use in connection with gas engines the "make and break" contacts are located within the cylinder. Reliable ignition is obtained when about 0.02 joule is dissipated in the spark at "break." Since the energy dissipated as heat in the spark is converted from the electromagnetic energy stored up in the coil, it follows that the coil must have an inductance and carry a current at "break" such that the energy stored up, i.e., $\frac{1}{2}LI^2$, will exceed the required value of 0.02 joule. In practice it is customary to design the coil and time of contact so that $\frac{1}{2}LI^2$ equals about 0.04 joule, such coils having an efficiency of about 50 per cent. One-half of the energy put into the coil is then used up in heating the conductors and metallic parts by I^2R and hysteresis losses.

SECONDARY INDUCTION COIL. — The secondary coil has two separate windings wound about an iron core, one of few turns called the primary winding and the other of many turns called the secondary winding. The primary winding is connected in series with a battery and an interrupter (described below). The spark is produced between the terminals of the secondary winding. In most cases a condenser is shunted across the interrupter to prevent sparking at

*This and the following oscillograph records are due to Bailey, B. F., *Elec. W. 1910, Vol. LV., p. 943.*

that point. Since the e.m.f. induced in each turn linked by the magnetic flux is the same, the e.m.f. induced in the secondary winding, neglecting leakage, will equal $\frac{N_s}{N_p}$ times that induced in the primary winding, where N_s and N_p equal the respective number of turns on the secondary and primary windings. Secondary coils which give sparks as long as 5 feet have been constructed in this manner.

Effect of Shunting Interrupter with Capacity. — When the interrupter is shunted by a capacity the e.m.f. induced in the secondary winding becomes oscillatory. This effect of the capacity is well shown in the oscillograph records given in Figs. 2 and 3. In each case a high *non-inductive* resistance is connected

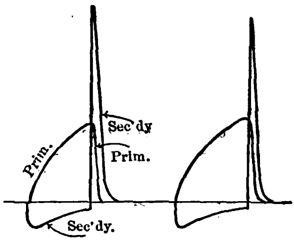

Fig. 2.

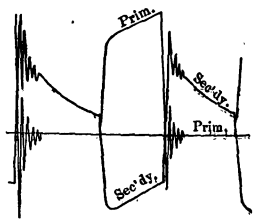

Fig. 3.

across the secondary terminals, and the curves indicate the variation of the primary current and the secondary e.m.f. In Fig. 2 the interrupter is unshunted by a condenser, and as a result the secondary e.m.f. increases at "break" and decreases to zero without oscillation. In Fig. 3 the interrupter is shunted by a condenser and the secondary e.m.f. becomes oscillatory. The form of the e.m.f. curve in any actual case is not shown accurately by Fig. 3 except at the time of "break," since the resistance between the terminals of a spark gap decreases rapidly after the spark is established. In Fig. 4 a low resistance is connected across the secondary terminals and shows the general form of the e.m.f. curve after the spark is established.

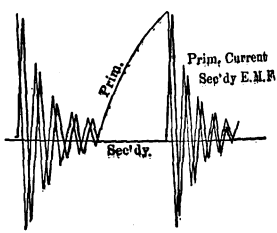

Fig. 4.

Although not shown by the curves owing to difference in scale, the capacity shunted around the interrupter also increases the secondary e.m.f. above the value obtained without the capacity. Assuming that no spark is formed at the interrupter, it may be shown that the e.m.f. of the secondary equals $\frac{N_s}{N_p}\sqrt{\frac{L}{C}}I_b$, where L equals the inductance of the primary in henries, C equals the capacity of the condenser in farads and I_b equals the primary current at "break" in amperes. If C is made so low that a spark appears at the interrupter, the above formula no longer holds and the secondary e.m.f. will be greatly reduced. C should then be made as small as possible but of sufficient size to suppress the spark at the interrupter.

Insulation. — The conductors in the secondary winding must be heavily insulated to withstand the very high e.m.f. induced in that winding. In most

cases a double-covered silk insulation impregnated with some insulating compound is used. In large induction coils the secondary winding is built up of several flat coils insulated from each other by ebonite or fiber disks. The coils are so wound that the electrical connections are made alternately at the top and at the bottom of the respective coils.

Dimensions of Three-inch Coil. — The general dimensions of parts of a 3-inch induction coil, as reported by S. R. Bottone, *Radiography (London, 1898)*, are given following: Iron, bundle of No. 20 (B. & S. G.) annealed iron wire, 1¼ in. diameter, 13 in. long. Primary winding, four layers of No. 12 double silk-covered copper wire, about 4¼ lb. Ebonite tube over primary, 12 in. long, 2 in. inside diameter, 2½ in. outside. Two ebonite heads, 5 in. square, ½ in. thick. Seven vulcanized fiber circlets (for sections), 4½ in. diameter, ⅛ in. thick, 2½ in. central aperture. Secondary winding, 4 lb. No. 36 double-silk-covered wire. Platinum-tip contact breaker, height from base to center of iron hammer, 2½ in., size of iron head of hammer ¾ in. diameter, ¾ in. long. Base (fitted with false bottom to contain condenser), 18 in. long by 9 in. wide by 2¾ in. deep. Condenser, 144 sheets of tinfoil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper 8 by 13 in.

Dimensions of Six-inch Coil.—Similar dimensions for a 6-inch induction coil, as reported by Bottone, are given following: Iron, bundle of No. 16 (B. & S. G.) annealed iron wire, 1½ in. diameter, 15 in. long. Primary winding, four layer of No. 12 double silk-covered copper wire, about 5 lb. Ebonite tube over primary 14 in. long, 2¼ in. inside diameter, 2¾ in. outside. Ebonite heads 6 in. square, ¾ in. thick. Seven vulcanized fiber circlets 5¼ in. diameter, ⅛ in. thick, with 2¾ in. central hole. Secondary winding, 7 lb. No. 38 double-silk-covered copper wire. Platinum-tip contact breaker, height from base to center of hammer, 3 in. size of hammer head, 1 in. diameter, 1 in. long. Base (fitted with false bottom to contain condenser), 20 in. long by 10 in. wide by 3½ in. deep. Condenser, 144 sheets of tinfoil, size 6 by 12 in., interleaved with 144 sheets of paraffined paper, 8 by 13 in.

Interrupters. — An interrupter should be so designed that it will close the circuit for a definite time by easy adjustment and will open the circuit at the end of that time as quickly as possible. Two distinct types, the mechanical and the electrolytic interrupter, are in common use. Mechanical interrupters may be divided into the following forms: hammer, atonic, commutator and mercury interrupters. Of the electrolytic interrupters the Wehnelt type is the most popular.

Hammer Interrupter. — In the hammer interrupter, shown in Fig. 5, the circuit is opened at *A* when the core *B* attracts the iron mass *C* mounted at the free end of the spring blade *D*. Since the core attracts the iron mass only when the circuit is closed and loses its attraction when the circuit is opened, the spring blade is set in vibration and opens and closes the circuit in rapid succession. This type is used extensively in connection with small coils. The contacts at *A* are usually tipped with platinum to withstand the intense heat developed by sparking. The rapidity of the "break" is not great enough for large coils, and when a large current must be broken, trouble is experienced in keeping the contact points in good condition.

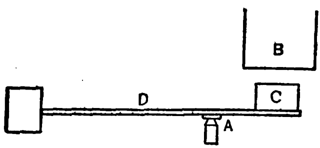

Fig. 5. Hammer Interrupter

Atonic Interrupter. — In the atonic interrupter, shown in Fig. 6, the free end of the iron strip *P* is attracted as in the hammer interrupter and is

returned to its original position by the spring *R*. The circuit is opened at the contacts *ab* when the free end of *P* strikes the blade *L*. Interrupters constructed in this manner open the circuit quicker than do the hammer type since the attracted member is moving faster at the instant of "break." The period of the atonic interrupter may be varied within wide limits by regulating the tension on the spring *R* by means of the thumb-screw *M*.

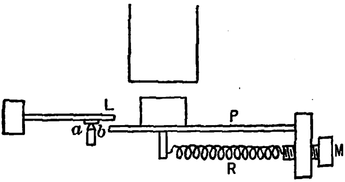

Fig. 6. Atonic Interrupter

Commutator Interrupters are often used when the primary current is too large to be broken by the hammer or atonic interrupters. A brush bearing upon a revolving disk, built up of conducting and insulating segments, makes and breaks the circuit at any desired rate, depending upon the speed of the motor which drives the disk.

Mercury Interrupters are specially adapted to circuits of high e.m.f. In the *plunger* type a pointed electrode is alternately immersed and withdrawn from a cup of mercury, the moving electrode being set in vibration magnetically as in the hammer interrupter, or by the positive action of a cam driven by a motor. The mercury cup is covered with a layer of oil so that the spark is quickly extinguished when the moving electrode is withdrawn into the oil. In the *turbine* type a small stream of mercury is directed upon the periphery of a revolving toothed wheel. The circuit is made when the mercury stream strikes a tooth and is broken when the mercury stream passes through a slot between the teeth. The toothed wheel is rotated at high speed by a motor which also drives a small mercury pump.

Wehnelt Interrupter. — The Wehnelt interrupter has two fixed electrodes which are immersed in dilute sulphuric acid. The anode consists of a small platinum wire insulated by glass except at its tip end. The cathode usually consists of a sheet of lead. If the electrolyte is well circulated, an interrupter of this kind will give about 450 interruptions per second with 24 volts impressed upon the primary circuit. When used with large coils the electrolyte heats up quickly, and a cooling coil is sometimes immersed in the electrolyte to control the temperature.

Tesla Coil. — In some cases, as in wireless telegraphy, electro-therapeutics, etc., where a unidirectional e.m.f. is not required, but an e.m.f. of high frequency is desired, a Tesla coil may be used in place of an induction coil. The construction of a simple Tesla coil is shown in Fig. 7. In the primary circuit a primary winding of few turns and a small spark gap are shunted by a condenser. Secondary and primary windings are wound together upon an air core. If an alternating e.m.f. of from 5,000 to 10,000 volts is impressed upon the primary the condenser is charged until the voltage across the primary gap breaks it down. The condenser then discharges through the gap, producing an oscillating current in the primary winding. The oscillating current in the primary induces a high-frequency e.m.f. in the secondary, which is sufficient to break down the long secondary spark gap.

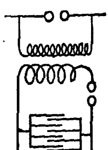

Fig. 7. Tesla Coil

[R. G. Hudson.]

INSULATING MATERIALS, MISCELLANEOUS. — (*See also Cambric, Varnished; Electricity and Magnetism, Principles of; Gutta Percha; Insulating Materials, Testing of; Paper, Impregnated; Rubber; Wires and Cables, Insulated.*) Materials used in the insulation of electrical apparatus may be classified as follows (*see also Standardization Rules of A.I.E.E.*):

1. Vitreous, including glass, enamel, etc., 2. Stony, such as slate, marble, mica, asbestos, porcelain, etc., 3. Osseus, such as bone and ivory, 4. Resinous, including shellac, resins, copal and other gum, 5. Bituminous, as bitumen, asphaltum, pitch, etc., 6. Waxy, including bees-wax, paraffin, etc., 7. Elastic, such as india-rubber, ebonite, gutta-percha, etc., 8. Oily, including various oils and fats of animal and vegetable origin as mineral petroleum, 9. Cellulose, including dry wood and paper, cotton, celluloid, etc., 10. Silk and allied animal tissue such as catgut, 11. Sulphur.

SELECTION OF INSULATING MATERIAL. — In selecting an insulating material for any special purpose and in predetermining accurately the behavior of such a material under working conditions, it is desirable that the following electrical, physical and chemical properties of the material should be known as far as they apply to the material in question.

Electrical. —

Dielectric strength (voltage per mm. or per in. at puncture).
Relative dielectric hysteresis.
Specific inductive capacity; Direct-current; Alternating-current.
Conductivity or insulation resistance. Surface leakage.

Physical. —

Specific gravity and specific weight.
Hardness.
Toughness.
Brittleness.
Ductility.
Workability.
Flexibility (with reference to varnished cloths, etc.).
Strength (tensile, compressive and shearing).
Fracture, (fibrous, crystalline or amorphous).
Ability to take polish.
Melting point.
Shrinkage.
Adhesiveness.
Effect of high temperature (electric arc).
Effect of low temperature.
Artificial aging test.
Porosity.
Viscosity.
Flash and fire test.
Film-making power.
Rate of drying.
Penetration.
Absorption of moisture.
Amount of volatile matter given off at prescribed temperatures.

Chemical. —

Proximate composition.
Solubility in water, oil, etc.
Effect of moisture and moist air.
Weathering qualities.
Chemical effect upon metals in contact.
Presence of acid.

As the testing of insulating materials (*see Insulating Materials, Testing of*) is not standardized and few authorities have investigated the subject, the existing data pertaining to insulating materials are scanty, disconnected, and in many cases unreliable. In the following pages available data are given concerning the important insulating materials, the materials being listed alphabetically. The puncturing voltage and the dielectric strength reported are presumably effective a-c. values for a sine wave; the reports of tests, however, are not always specific on this point.

Adit is a form of papier-maché impregnated and covered with a special insulating compound. It may be moulded accurately in any form and possesses a tensile strength of about 130 kilograms per sq. cm. Certain grades of Adit withstand heat up to 60° C., others up to 120° C. It does not support combustion and its insulating properties are stated to be unaffected by dampness. The voltages required to puncture sheets of various thicknesses are given as follows (Hobart and Turner):

Thickness in mm.	2	3	4	5
Volts at puncture	1000	1800	3000	4000

Aetna Material is a composite material, used principally for strain insulators. Symons gives the following results of tests made upon a strain insulator constructed of Aetna material: puncturing voltage, 11,000; insulation resistance 20,000 megohms; tensile strength, 2.46 tons per square inch; a sample immersed in water at 120° F. absorbed 3.17 per cent of its own weight in 1.5 hours. Aetna material will withstand great heat without disintegration but is inclined to be brittle at high temperatures.

Air has a low conductivity and specific inductive capacity, and a dielectric strength sufficient for most purposes except very high voltage apparatus and transmission lines; see articles on *Corona* and *Spark Gap*.

Ambroin is made by baking in a vacuum silicate of sodium, asbestos, fossil copals, etc., mixed with alcohol. It is moulded in heated moulds, under high pressure. Certain grades of Ambroin will resist very high temperatures and are suitable for use in arc shields. The tensile strength of grade A. F. is 2140 pounds per square inch and the compressive strength is 2680 pounds per square inch, both tests being made at room temperatures. Ambroin is only slightly hygroscopic as compared with other insulators of the same nature. (Adapted from Hobart and Turner.)

In tests made by the German Reichsanstalt the voltages required to puncture specimens of Ambroin of grade A. F. of various thicknesses were found to be as follows:

Thickness in millimeters	0.33	0.84	5.0
Volts at puncture	3500	over 5000	over 36,000

The insulation resistance of a specimen 3 mm. thick and 25 sq. cm. in area was found to be 200,000 megohms.

Asbestos is a mineral consisting chiefly of silica, magnesia, lime, alumina, water and oxide of iron. The fibrous variety, called amianthus, is used in the manufacture of asbestos paper, cardboard, yarn and cloth. It is unaffected by oils, acids and alkalies and withstands very high temperatures. As a non-conductor of heat, it has an extensive use as an insulator in heating devices.

According to Stifler its insulating qualities break down at 1000° C. but recover after the asbestos is cooled. At temperatures above 1000° C., asbestos loses its mechanical strength and melts at about 1300° C. Steinmetz gives the following puncturing voltages for asbestos paper:

Thickness in millimeters	0.6	1.2
Volts at puncture	2700	5000

Whittaker's Pocket Book gives the insulation resistance as 16×10^4 megohms per centimeter cube.

Asphalt is a mineral pitch found in geological formation in various parts of the world. Asphalt is used (1) in the manufacture of insulating varnishes and japans, (2) for the impregnation of hygroscopic non-waterproof insulating materials and (3) as an insulating covering for cables. The various grades of

asphalt used for electrical work are called Trinidad, Bitumen, Elaterite, Gilsonite, Byerlyte and Manjak. Asphalt insulators possess a high insulation resistance, dielectric strength, flexibility and mechanical toughness, are very cheap, and are unaffected by moisture.

Pure asphalt (solid bitumen) softens at from 90° to 100° C. and is not recommended for use for immersion in hot oils, or where it would be subjected to centrifugal stress. Certain grades of Byerlyte melt at temperatures ranging from 200° to 350° F., while the melting point of Gilsonite varies from 230° to 400° F. Symons states that the dielectric strength of pure asphalt is 30,000 volts per inch (test made on sheet 1/16th inch thick). The manufacturers (Byerley & Sons, Cleveland, O.) state the dielectric strength of Byerlyte to be as follows:

Thickness in mils	140	215	430
Time of application	10 sec.	4 min.	5 min.
Dielectric strength, volts per inch	50,000	50,000	50,000

Pirani gives the value 2.68 for the specific inductive capacity of pure asphalt.

Bakelite is a synthetic organic substance resulting from the chemical condensation of phenols and formaldehyde (General Bakelite Co., N. Y.). It may be applied as a liquid or used as a solid. The liquid Bakelite is useful for the impregnation of porous materials, for enameling under heat and pressure and as a binding agent for moulded compounds. The solid Bakelite is unaffected by water, steam, oils and almost all chemicals. It does not melt or soften at ordinary machine temperatures; it is destroyed only at temperatures in the vicinity of 300° C. It is easily and accurately moulded and may be made to take any color It compares favorably with rubber and gutta-percha in every way except that it is not as flexible as those substances. The following data regarding Bakelite are given by the manufacturers:

PROPERTIES OF BAKELITE

Composition	Thickness of testing piece in millimeters	Volts at puncture	Volts per millimeter at puncture*
Different varieties of transparent "C" made especially for electrical purposes by hardening liquid "A" on a glass plate in a stove.	1.78	......	17,400
	2.18	......	14,200
	2.60	......	13,400
	0.43	16,750	38,800
	0.80	23,300	28,000
	0.95	25,600	26,900
Moulded composition, 70% Asbestos, 30 % Bakelite	8.0	......	8,500
Moulded composition: wood, flour and Bakelite	7.9	......	11,000
Impregnated blotting paper, hardened in a hot hydraulic press	3.66	102,000	27,880
Pressed paper impregnated with Bakelite	1.6	53,700	33,500

* Tested with a 50-kilowatt transformer, raising voltage gradually so that puncture occurred within 20 or 30 seconds.

Item	Bakelite and wood pulp	Bakelite and asbestos
Specific resistance in megohms per cm. cube	35×10^6	10^4
Tensile strength, lb. per square inch	650	1200
Compression strength, lb. per square inch	4000	18,000
Maximum working temperature, ° C.	90	450

The specific inductive capacity ranges from 5.60 to 8.85, depending upon the composition.

Berrite is a gum used for impregnating paper and cloth. Materials impregnated with it are tough but crack easily. It runs freely at low temperatures and is unaffected by high temperatures. The dielectric strength is given by Hobart and Turner as 5000 volts per millimeter.

Bitumen. — See section on *Asphalt.*

Byerlyte. — See section on *Asphalt.*

Cambric, Varnished. — See separate article on *Cambric, Varnished.*

Celluloid (xylonite) is a dried solution of gun-cotton (pyrolin) and oil. It may be machined or moulded into any form by softening in boiling water. Its dielectric strength is very much reduced at high temperatures, and it is very combustible. It is only slightly hygroscopic. Hobart and Turner give the following values for its dielectric strength:

	Volts per mm.
Clear samples, 0.25 millimeter thick, 20° C.	12,000-28,000
Clear samples, 0.25 millimeter thick, 100° C.	4,000-12,000
Colored samples	10,200-18,900

Tests made at the Stadt. Lab., Munich, give for the insulation resistance 71×10^3 megohms per centimeter cube.

Coal-tar Pitch is the residue remaining after the fractional distillation of coal tar. It flows at low temperature and when cold is quite brittle. Symons gives its dielectric strength as 2000 volts per millimeter.

Copal is a resinous substance, which makes a colorless varnish when dissolved in alcohol, oil of turpentine or linseed oil. Copal is easily fused, is very inflammable and is quite brittle when cold. Steinmetz gives the following puncturing voltages: 9700 volts at 3.0 millimeters and 20,400 volts at 6.0 millimeters.

Condensite is made by the Condensite Co. of America, Glen Ridge, N. J., and by the Dickinson Mfg. Co., Springfield, Mass. It is a hard infusible substance, the chief constituent of which is a resinous gum, made by the reaction between phenol and formaldehyde. Condensite is produced by combining this gum under heat with a hardening agent. It is supplied in three grades; for plastic moulding, for impregnating and as a cement. The moulded Condensite has a compressive strength of 25,600 pounds per square inch and tensile strength of 4270 pounds per square inch.

It is non-flammable and infusable, insoluble in oils, most acids and other solvents and shrinks but one-fifth of one per cent in moulding. The impregnating material is used in connection with metal, wood, paper, cardboard, rubber, leather, etc. The plastic cement is used for fastening together the parts of porcelain insulators, for sealing terminals in porcelain bases, etc.

Results of tests made upon Condensite by the Elec. Test. Lab. of N. Y. City, follow:

Thickness in mils	189	152	147
Temperature, degrees Fahrenheit	Room temp.	75	170
Dielectric strength, volts per inch	65,600	60,500	27,900

Ebonite. — See section on *Rubber, Hard*.

Eburin is a mixture of infusorial earth, asbestos, or cotton and gums, and may be moulded into any form. As it is not hygroscopic and is very strong, it is used frequently for out-door strain insulators (*Hobart and Turner*).

Elaterite. — See section on *Asphalt*.

Empire Cloth consists of a closely-woven cambric coated with two or more films of an oxidized oil, prepared by a secret process. Canvas, duck, linen, silk, and paper are also coated by the same process.

The Mica Insulator Co. give the puncturing voltages for various grades and thicknesses of Empire cloth as follows:

	Canvas	Linen	Muslin		Silk	
Thickness in mils	16	6	4	15	4	6
Volts at puncture	7800	7800	4200	15,000	4500	7225

Fiber. — Horn fiber (red, black, white and grey) has a very great tensile and dielectric strength. While not soluble in water, most acids or alkalies, it swells when immersed in water. The dielectric strength may be greatly increased by impregnating the material with oil or varnish. It will not melt at any temperature.

Vulcanized fiber, made of chemically-treated paper fiber, is made into sheets, tubes, rods and special shapes. It warps and shrinks badly and absorbs moisture. It has a tensile strength of 12,000 to 14,000 pounds per square inch and a compressive strength of 38,000 to 40,000 pounds per square inch. The dielectric strength is claimed to be independent of the thickness. Vulcanized fiber is insoluble in water or natural oils. Some of the strong acids will destroy it or make it brittle.

Miscellaneous fibers are manufactured by secret processes, many of them containing wood-pulp or asbestos.

PUNCTURING VOLTAGE OF VARIOUS FIBERS

Grade of fiber	Thickness	Volts at puncture	Authority
Dry wood fiber	0.22 mm.	2,800	Steinmetz
Dry wood fiber	1.69 mm.	21,600	Steinmetz
Red fiber	30.9 mils	8,000 to 9,500	Canfield and Robinson
Black fiber	70.9 mils	7,200	Canfield and Robinson
Vulcanized fiber	0.58 mm.	2,200	Steinmetz
Vulcanized fiber	12.8 mm.	22,500	Steinmetz
Vulcanized fiber	187 mils	10,000 to 12,000	Am. Vulc. Fiber Co.
Vulcanized fiber	375 mils	25,000 to 90,000	Am. Vulc. Fiber Co.
Horn (undried) fiber	0.56 mm.	5,990	Hobart and Turner
Horn (dried) fiber	0.56 mm.	6,880	Hobart and Turner
Horn (varnished) fiber	0.66 mm.	8,120	Hobart and Turner

Hendricks gives the curve in Fig. 1 for the puncturing voltage of hard fiber, the conditions being as follows:

Curves. — Measured on single thicknesses.

Dimensions. — 0.031-inch to 1-inch sheets.

Composition. — Chemical hard fiber.

Treatment. — Dried before testing.

Method of test. — Between flat, square cornered disks under oil.

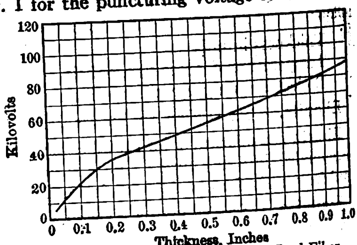

Fig. 1. Puncturing Voltage for Hard Fiber

Temperature. — 20 to 25° C. *Time.* — One minute. *Frequency.* — 60. *Wave.* — Sine.

Accuracy of curve. — About 10 per cent plus or minus.

Characteristics. — Results depend largely on dryness of fiber.

Notes. — Results on fiber of different colors seem to be identical.

Fuller-Board. — See section on *Pressboard*.

Galalith is made by heating the residue of skimmed milk after the water has been extracted. It is easily moulded or bent but is highly hygroscopic. Walter gives the dielectric strength as 6000 to 8500 volts per millimeter.

Gilsonite. — See section on *Asphalt*.

Glass is a silicate of soda or potash combined with certain metallic oxides, usually lead oxide. Owing to the condensation of moisture upon its surface, glass has a very large surface leakage. Rain water roughens its surface and the resulting accumulation of dirt reduces its insulating qualities. According to Gray and Dobbie the specific resistance of potash glass is higher than that of soda glass. Annealed glass has in general a higher specific resistance than unannealed glass. As compared with porcelain, glass is inferior in mechanical strength; whereas porcelain is only chipped by a blow, glass is easily cracked or shattered.

DIELECTRIC STRENGTH AND SPECIFIC RESISTANCE OF GLASS

Grade	Volts per mm. (*a*)	Megohms per cm. cube (*b*)
Common glass	8,000 to 9,000	99×10^7
Lead glass	5,500	25×10^5
White alabaster glass	11,500	33×10^8
Black alabaster glass	8,500	84×10^6 to 85×10^4

(*a*) Walter. (*b*) Foussereau (*see Bibliography*).

In various samples tested by Löwe and v. Pirani, the specific inductive capacity varied from 5.5 to 9.1.

Gohmak, made by the Vulcanized Products Co., Muskegon, Mich., is a moulded insulation of specific gravity 1.37 to 1.75, depending upon the compounding formula. The tensile strength varies from 9000 to 12,000 pounds per square inch. It will soften slightly at a temperature of 100° C. It is claimed

to be unaffected by immersion in water, oils, dilute acids and alkalies. The manufacturers state that sheets ⅛-inch thick are punctured by 50,000 volts and that the insulation resistance of Gohmak in megohms per centimeter cube is 17×10^3 at 28° C. and 9×10^3 at 50° C.

Gummon, made by the Dickinson Mfg. Co., Springfield, Mass., is made by a secret process. It is heatproof up to 700° F. and can be moulded when cold. It is not easily sawed or drilled as it takes the temper out of steel.

Gutta-Percha. — See article on *Gutta-Percha.*

Isolit, like ambroin, is a form of papier-maché, impregnated and covered with a special insulating compound. See section on *Ambroin.*

Jute is a fiber obtained from the inner bark of certain trees growing in India. Commercial jute is usually softened and rendered less brittle by impregnating it with paraffin or some similar mineral oil. It is used extensively as a filler in lead-covered cables and as a constituent of certain kinds of paper and press-board. Baur gives the following values of the puncturing voltage for impregnated jute:

Thickness in millimeters	3	6	12	24
Volts at puncture	4,800	7,200	12,000	19,000

Coyne and Howe give the specific inductive capacity of impregnated jute as varying from 3.0 to 4.0.

Lava, made by the Colonial Mfg. Co., Am. Lava Co., and Stewart Mfg. Co. of Chattanooga, Tenn., is a mineral talc, machined in its natural condition and then baked at a temperature of 1100° C. to a condition of extreme hardness. It is then unaffected by any subsequent temperature short of its baking temperature. It is slowly attacked by hydrochloric acid but is not affected by other acids or alkalies. Its dimensions are unchanged by absorption of moisture and it has a negligible coefficient of expansion with temperature. The dielectric strength varies from 250 to 75 volts per mil depending upon the thickness of the sample tested.

Lavite. — See section on *Lava.*

Leatheroid. — See section on *Fiber.*

Litholite is an insulating material resembling psychiloid in structure. It is made in sheets and is pressed into any form. It is softened by sulphuric acid and distilled water and is reduced to a pulp if immersed in caustic soda. It is tough but inflammable. It is used for commutator rings, bushings, washers, formers, bobbins and for square and round tubing. Symons states that 20,000 volts is required to puncture a thickness of 0.445 centimeter.

Marble is the name given to any limestone which is sufficiently compact to admit of a polish. While pure marble is white, the presence of iron oxide or other impurities give it different colors. It is used principally for switchboard work and should not contain metallic veins, which reduce its insulating qualities. According to Walter the dielectric strength of marble is 6500 volts per millimeter. Schmidt gives the specific inductive capacity of Carrara marble as 8.3. The insulation resistance, from tests made at Stadt. Lab., Munich, is stated to be 435 to 510 megohms per centimeter cube.

Megohmit is a form of reconstructed mica in which the adhesive matter is reduced to a minimum and does not exceed 1.25 per cent of the finished product. The hard megohmit plates soften at about 80° C. It is used for slot insulation, commutator rings, collars, etc. Hobart and Turner give the following values for the puncturing voltage:

Thickness in millimeters	0.25	0.6	1.0
Volts at puncture	8,000	20,500	36,000

Mica is an anhydrous silicate of aluminum and potash or sodium. It crystallizes in a laminated mass, some grades of which may be subdivided down to a thickness of 0.006 millimeter. It is useful as an insulator because of its high insulating qualities and its ability to withstand high temperatures. Owing to its impurity, lack of flexibility and excessive surface leakage in the natural state, the laminæ are separated and sorted into various grades of purity and are then cemented together to form plate or flexible reconstructed mica of any thickness or purity. Moulded mica is used in the manufacture of overhead line material and in the making of moulded pieces as a substitute for hard rubber. Moulded mica softens at 136° F. It is insoluble in water, but is affected by certain oils and all acids and alkalies to some extent. Mica loses its insulating qualities at a temperature of 1000° C., but recovers them after cooling. Andrews showed that the dielectric strength of mica is greatly reduced when immersed in or coated with oil.

DIELECTRIC STRENGTH OF MICA

Grade	Thickness, mils	Volts per millimeter	Volts at puncture
	...	28,000 (a)	....
German E. Africa	...	17,500	....
Calcutta	...	24,500	....
Madras	...	21,000	....
Russia	...	20,000	....
Ceylon	...	....	5000 (b)
....	1.7	....	5400
....	2.8	....	6200
....	3.2	....	6100
....	5.1	....	

(a) Walter, B. (b) Canfield and Robinson (*see Bibliography*).

Curie states that the insulation resistance of mica at 20° C. is 88×10^8 megohms per centimeter cube. Starke states that the specific inductive capacity varies from 5.8 to 7.7.

Micabond Cloth, Paper and Plate, made by the Chicago Mica Co., Valparaiso, Ind., are forms of reconstructed mica. Micabond cloth is made of muslin, India mica and paper, the binding material being gutta-percha tissue. It is made in thicknesses of 12, 15 and 18 mils respectively for use in armature slots, cores, coils, etc. The dielectric strength is 435 volts per mil. Micabond paper is made of Japanese paper, mica and rubber. It is made in thicknesses of 6, 9 and 11 mils respectively for use in armature slots, coils, etc. Its dielectric strength is 1012 volts per mil. Numbers 101 and 111 are easily moulded when heated, whereas numbers 102, 104, 122 and 144 cannot be moulded, particular attention being given to these grades to secure a uniform thickness for commutator use.

Micanite, made by the Mica Insulator Co. of New York, is a form of reconstructed mica. The puncturing voltage for micanite plate, used for commutator segments, ranges from 9540 volts for a thickness of 10 mils to 119,000 volts for a thickness of 125 mils. The puncturing voltage for flexible micanite, used for armature slots, armature, magnet and commutator cores, transformers, etc., ranges from 2940 volts for a thickness of 5 mils to 73,500 volts for a thickness of

125 mils. Micanite cloth is constructed of layers of mica, muslin and Japanese paper and the average puncturing voltage for thicknesses of from 12 to 18 mils is 4350 volts. Another grade of micanite cloth is constructed of mica, rubber tissue and Japanese paper. Its average puncturing voltage for thicknesses of from 12 to 18 mils is 4000 volts. Micanite paper, constructed of mica and Japanese paper, has an average puncturing voltage of 3700 volts for thicknesses of 6 to 11 mils. When constructed of mica, rubber tissue and Japanese papers the average puncturing voltage for thicknesses of 6 to 11 mils is 3675 volts. Rope paper and mica, 7 to 15 mils thick, breaks down at about 4800 volts and pressboard and mica, 7 to 15 mils thick, breaks down at 5500 volts.

Minerallac, made by the Minerallac Elec. Co., Chicago, Ill., is an insulating compound, made in four grades as follows: No. 1, a fluid of the consistency of molasses, No. 2, a semi-solid compound resembling hard rubber, No. 3, a heavy dark-brown impregnating liquid, and No. 5, a capping compound used for sealing apparatus after impregnation. The following results were obtained from tests made upon Minerallac No. 2 by Elec. Test. Lab. of N. Y.: dielectric strength, approximately 1000 volts per mil; insulating resistance 1.3×10^9 megohms per inch cube; specific inductive capacity, about 2.1 at 75° F.; softening point, 118° F.; melting point, 146° F.; flash-point, 395° F.; fire-point, 425° F.; acid or alkali reactions, none.

Oil. — See article on *Oil, Transformer.*

Paper. — See article on *Paper, Impregnated.* Unheated paper is suitable for insulation only when inclosed in an air-tight envelope (e.g., a telephone cable), for paper is very hygroscopic. Unheated dry paper from 3.5 to 4.5 mils thick punctures at about 800 volts according to Canfield and Robinson. The specific resistance depends largely upon the quality of the paper, being of the order of 5×10^4 megohms per centimeter cube. The specific inductive capacity of the paper used in telephone cables, as given by various authorities, ranges from 1.7 to 3.8.

Paraffin is a product obtained by the destructive distillation of petroleum shale. The dielectric strength of cloth, wood and paper is increased by impregnation with paraffin and the materials are rendered less hygroscopic. Paraffin is acidproof but is very inflammable and has a low melting point, about 65° C. The dielectric strength of solid paraffin is given by Walter as 11,500 volts per millimeter. Steinmetz gives 7690 volts per millimeter as the dielectric strength of melted paraffin. The insulation resistance according to Braun is 284×10^{10} megohms per centimeter cube. According to Zietkowsky the specific inductive capacity ranges from 2.105 at 44° C. to 2.165 at 76° C.

Porcelain. — (*See also article on Insulators, for Overhead Lines.*) Porcelain for electrical purposes has a specific gravity of 2.65. It is unaffected by oils, acids or alkalies. The Locke Insulator Mfg. Co. gives the tensile strength as 1500 pounds per square inch and the compressive strength 15,000 pounds per square inch. It is quite brittle and cannot be moulded accurately enough for use in some cases. Ink placed upon good porcelain at a fracture will not flow from the part initially inked.

The puncturing voltage is as follows;

Thickness in millimeters	10	20	30
Volts at puncture	115,000	160,000	190,000

The insulation resistance is as follows:

Temperature, °C.	50	400	1000
Megohms per cm. cube	215×10^7 (*a*)	20 (*b*)	1 (*b*)

(*a*) Foussereau. (*b*) Goodwin and Mailey.

The Locke Insulator Mfg. Co. gives the specific inductive capacity as 4.4.

Pressboard is similar to paper in its construction, except that it is thicker and less flexible. It is usually hygroscopic unless impregnated with some moisture repellant. It is pressed into many useful forms, and is used as an insulator

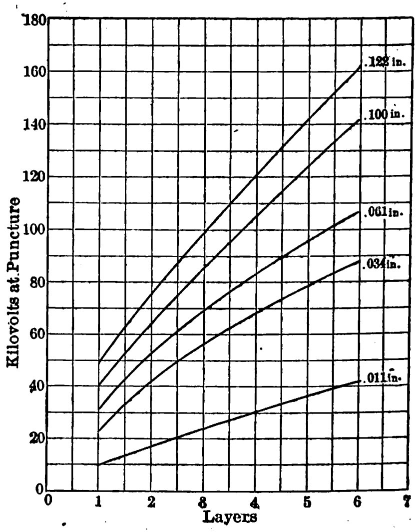

Fig. 2. Puncturing Voltage for Oiled Pressboard

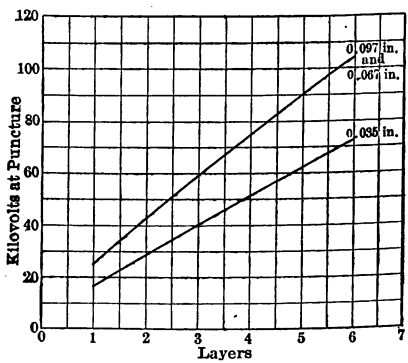

Fig. 3. Puncturing Voltage for Varnished Pressboard

principally in connection with low voltages. See sections on *Fiber*, *Paper*, etc., for other properties.

Figs. 2 and 3 from Hendrick's paper show the dielectric strength of oiled and varnished pressboard respectively.

OILED PRESSBOARD

Dimensions. — 0.011 inch to 0.122 inch thick — one to six layers.

Composition. — Cotton rags and paper clippings.

Treatment. — Dried and boiled in transformer oil.

Method of test. — Between square-edge flat disks 4 inches in diameter under oil.

Temperature. — 20 to 25° C. *Time.* — 1 minute. *Frequency.* — 60. *Wave.* — Sine.

No. of trials. — Each point, one to four.

Accuracy of curve. — 10 per cent plus or minus. Curve is based on but a few trials, hence is not very reliable, but shows typical results.

Characteristics. — Material is variable; results depend largely on time of application of stress.

Specific capacity. — 4.9 at 20 to 25° C. under oil.

Notes. — Total time of test is about 5 minutes (average) giving rather low results.

VARNISHED PRESSBOARD

Dimensions. — 0.035 inch, 0.067 inch and 0.097 inch thick — one to six layers.

Composition. — Cotton rags and paper clippings.

Treatment. — Dried and given two coats of varnish.

Method of test. — Between square-edge flat disks 4 inches in diameter under oil.

Temperature. — 20 to 25° C. *Time.* — 1 minute. *Frequency.* — 60. *Wave.* — Sine.

No. of trials. — Each point, one to four.

Accuracy of curve. — 10 per cent plus or minus. Curve is based on but a few trials hence is not very reliable but shows typical results.

Characteristics.—Dielectric strength low but fairly uniform, depending largely on varnish film; nearly proportional to total thickness within limits of tests.

Specific capacity. — 2.9 at 20 to 25° C. on 0.097-inch board.

Presspahn is a type of pressboard made in Germany. It is strong and can be easily bent. It is usually impregnated and boiled in pure linseed oil, thinned with benzine.

Kinzbrunner gives the dielectric strength of presspahn in volts per millimeter as ranging from 9300 to 5200, the puncturing voltage decreasing as the radius of the test electrodes increases. The insulation resistance from tests at the Stadt. Lab. Munich is given as 11×10^3 megohms per centimeter cube.

Psychiloid consists of a paper pulp, which is cured, dried and then treated chemically. According to Hobart and Turner it may be machined and worked into any form and is pressed into sheets varying from 1/16 to 1½ inches in thickness. It is stated to be non-absorbent and unaffected by oils. Symons gives the volts at puncture as 25,000 for a thickness of 3.2 millimeters.

Rubber. — See article on *Rubber*.

Resin is the oxidized exudation of certain trees or plants and may be of recent origin or exist as a fossil. Some of the common resins which are used for insulating purposes are mastic, shellac, jalap, turpentine, storax, amber, hartite, ozokerite, copal, kauri-gum, etc. Most resins are insoluble in water but dissolve in alcohol, ether, etc., forming varnishes of high dielectric strength. The resin varnishes are limited in their use by the fact that they become brittle at high temperatures, and will disintegrate if under vibration. Resins are hygroscopic and in general possess undesirable acid properties. Tests made by various authorities of the specific inductive capacity of the various resins indicate a value between 3.9 and 4.0.

Slate is hygroscopic and should be boiled in paraffin. It is often permeated by metallic veins, making it unfit for use unless the electrical connections are

insulated by bushings. It is useful for switchboard and switch-base work owing to its desirable mechanical and fireproof qualities. Its dielectric strength decreases rapidly as the temperature increases, and at a high temperature slate becomes a conductor. Where a high voltage is impressed upon a piece of slate for some time, the slate usually is not punctured but, due to the consequent rise in temperature, the slate acts as a short-circuit to the impressed voltage.

The breakdown is thus only apparent as the specimens regain their dielectric properties after cooling. Values of this breakdown voltage, as determined at the Massachusetts Institute of Technology in 1913, are as follows:

Thickness in mm.	3.7	7.2	10.3	13.5	25.3
Volts at breakdown	11,300	10,800	13,700	12,200	22,500

Schulze gives the specific inductive capacity of slate as varying from 6.60 to 7.37. The insulation resistance of slate, as determined at the Stadt. Lab., Munich, is 78×10^3 megohms per centimeter cube.

Varnished Cambric. — See article on *Cambric, Varnished.*

Varnishes, Insulating, are made in two classes: (1) baking varnishes, which harden by oxidation when subjected to artificial heat and (2) air-drying varnishes and similar compounds, which harden or set by evaporation of the solvent. Varnishes and similar compounds are manufactured in a number of grades adapted for use in connection with armature, field, and transformer coils, magnet and arc lamp spools, transformer bushings, insulating cloth, paper and fiber, armature and transformer stampings, asbestos and magnesia board, cut-out boxes, switch and panel boards, mica plate, flexible mica, mica cloth and paper, storage batteries, weatherproof wire, iron and metal fittings, moulding, potheads, vacuum impregnating, taped connections, etc. Some of the trade designations are P. and B., S. P. C., S. V. W., G. P., H. R., Voltalac, W. P., Glinolac, Benolite, Dolph's, Ohmlac, Minerallac, Nico, M. C., Insullac, Enamelac, Armalac, Chatterton, Linolac, M. I. C., etc.

Vulcabeston is a compound of asbestos and rubber, the asbestos predominating. It is used in the form of moulded insulating pieces in connection with electrical machinery where a material is desired which is not affected by oils and which will withstand a high degree of heat. Although insoluble in water and unaffected by oils, it is slightly disintegrated by acid and alkaline solutions. It softens at temperatures ranging from 300 to 600° F., depending upon the grade. The above data are given by Holitscher. The puncturing voltage of vulcabeston, according to Canfield and Robinson, is 4000 volts for a thickness of 42.8 mils and 6000 volts for a thickness of 75.4 mils.

Vulcanite. — See article on *Rubber.*

Wood. — Thoroughly dried hard wood, if impregnated with an insulating material, makes a good insulator. The woods commonly used are maple, cherry, ash and yellow pine. For use in transformers, wood is usually impregnated with transformer oil, and when used in air, the wood is impregnated with paraffin or rosin. Fig. 4 from Hendrick's paper gives the puncturing voltage of oiled wood. The conditions under which the tests were made are as follows:

Material. — Hard maple.

Dimensions. — ½ inch to 1 inch across grain; 1 inch to 6 inches with grain.

Treatment. — Across grain, boiled in transformer oil under vacuum; with grain, dried under vacuum, boiled at atmospheric temperature.

Method of test. — Between square-cornered flat disks under oil.

Temperature. — 20 to 25 °C. *Time.* — 1 minute. *Frequency.* — 60. *Wave.* — Sine.

No. of trials. — Each point, one to three; three points across grain; five points with grain.

Accuracy of curve. — 10 per cent plus or minus.

Characteristics. — Dielectric strength across grain increases much slower than thickness but with the grain is proportional to thickness.

Specific capacity. — Across grain = 4.1 at 20 to 25° C. under oil.

Notes.—Test with and across grain on samples treated by different methods a long time apart. Wood seems to be identical in quality however.

The insulation resistance and specific inductive capacity of various woods are as follows; the specific inductive capacities are from tests by Starke; the insulation resistance from tests by various experimenters.

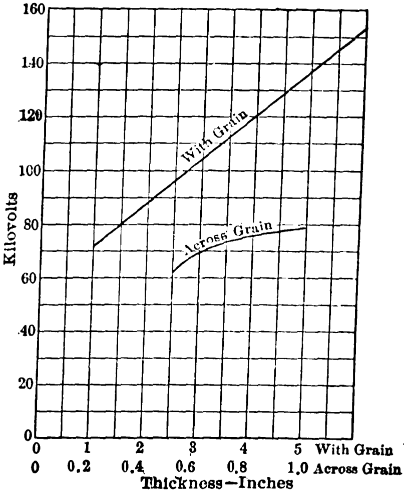

Fig. 4. Puncturing Voltage for Wood

Kind of wood	Megohms per cm. cube	Kind of wood	Specific inductive capacity
Beech	5×10^6–6×10^4	Red beech (parallel to fiber)	2.51–4.83
Pine (parallel to fiber)	35×10^9	Red beech (perpendicular to fiber)	3.63–7.73
Pine (perpendicular to fiber)	10×10^{10}	Oak (parallel to fiber)	2.46–4.22
Walnut (dry)	53–133	Oak (perpendicular to fiber)	3.64–6.84
Walnut (paraffined)	8×10^2–124×10^2

[R. G. Hudson.]

INSULATING MATERIALS, TESTING OF. — (*See also Insulating Materials, Properties of.*) The most important electrical properties of an insulating material are its dielectric strength, its specific inductive capacity, its insulation resistance and its effective a-c. conductance. Some of the more common methods of measuring these quantities are described below.

DIELECTRIC STRENGTH. — The dielectric strength of an insulating material is defined as the puncturing voltage per unit thickness, the thickness usually being measured in millimeters or mils. The voltage required is in general higher than can be obtained with direct-current sources of e.m.f. and alternating e.m.f.'s are therefore used in such tests. The materials to be tested are placed between electrodes connected to the high-tension terminals of a transformer, which receives power from a low-voltage alternator.

Testing Transformers and Alternators. — Transformers for such use are made to deliver voltages up to 500,000 volts. For the purpose of comparison and computation of the maximum e.m.f. from the effective value, it is essential that the alternator should give a sine-wave voltage at all loads. Both transformer and alternator should be large enough to operate with good voltage regulation at all testing loads, so that no distortion of the wave-form will be produced by the charging current. Skinner suggests the following ratings of testing transformers:

Max. test voltage	Cap. of trans. in kw.	Max. test voltage	Cap. of trans. in kw.
2,000	1	50,000	50
6,000	3	100,000	100
10,000	5	150,000	150
30,000	30	250,000	250

The alternator should have a distributed field winding and in order that the combination of alternator and transformer may respond to any instantaneous load, the impedance of each should be low; that is, the speed of the alternator should be high and the e.m.f. induced per turn in the transformer should be high.

Form of Electrodes. — Many investigators have demonstrated that the form of the electrodes used is an important factor of the test. If the edges of the electrodes are rounded, the resulting brush discharge heats the specimen so that it breaks down at a low voltage. If the edges of the electrodes are not rounded, the increased flux density at the edges produces an excessive strain on the dielectric under the edges of the electrodes. Most authorities favor the use of flat electrodes with slightly rounded edges. Hendricks suggests flat electrodes with corners rounded to a radius equal to one-tenth of the diameter of the flat face. Kinzbrunner has discussed in detail the effects of various shapes of electrodes.

For testing oils or other liquids two standards composed of definitely shaped terminals supported in a liquid container are commonly used. In one the testing terminals consist of brass balls ½ inch in diameter fastened to rods $\frac{3}{16}$ inch in diameter and placed vertically in a glass tube. The distance between the balls is adjustable, a distance of 0.15 inch, however, being considered standard. In the other standard the terminals consist of brass disks ½ inch in diameter mounted on rods $\frac{3}{16}$ inch in diameter and placed horizontally in a small box made of wood

or some other insulating material. The spacing of the disks in this case is also adjustable, although 0.2 inch is adopted as a standard. Average dry oil should not break down in the ball electrode standard at less than 30,000 volts and in the disk electrode standard at less than 45,000 volts.

Time of Electrification. — Materials may be tested by impressing the puncturing voltage, 1. instantaneously, 2. in steps of one-minute duration or 3. in several instantaneous applications of decreasing voltage and increasing time of electrification. The question of the proper time of electrification is at present undecided, although many investigators favor the one-minute electrification. For arguments against this standard, see paper by Kinzbrunner (reference in Bibliography at end of this article).

Control of Voltage. — The voltage impressed between the test electrodes may be controlled 1. by varying the excitation of the alternator, 2. by inserting resistance in series with the low-voltage terminals of the transformer or 3. by varying the number of active turns on the low-tension side of the transformer. A combination of the first and third methods is most commonly used. In the second method the voltage wave is made more peaked as resistance is introduced; in the third method, if used alone, the circuit must be broken as connections are made to the tap leads. By varying the field excitation of the alternator and changing the tap connections between tests, the shape of the voltage wave is kept constant and the variation of field saturation in the alternator is reduced to a minimum.

Measurement of Voltage. — The voltage impressed upon the material under test may be determined by 1. a variable spark gap shunted across the electrodes, 2. by a voltmeter and an extension coil or multiplier connected across the electrodes, 3. by an electrostatic voltmeter connected across the electrodes, 4. by a voltmeter connected across the low-tension terminals of the transformer, the reading of which is to be multiplied by the ratio of transformation of the transformer, 5. by a potential transformer and a voltmeter connected across the terminals and 6. by a special voltmeter winding placed in the middle of the high-tension winding of the power transformer. The needle spark-gap method, while convenient because of its indication of the maximum rather than the effective value of the voltage, is tedious in use, and its readings are dependent upon the time of electrification, circulation of air, the condition of the needles, etc. The sphere spark gap is preferable; see *Spark Gap*. The use of the voltmeter and extension coil, while flexible and convenient, is not recommended because of the load which is placed upon the transformer and the possibility of leakage in the extension coil. The use of an electrostatic voltmeter is desirable, except that at high voltages the moving element must be immersed in oil, making the instrument sluggish in action, and may frequently break down. In any method involving the ratio of transformation of the transformer, the results are questionable owing to the assumption of a constant ratio of transformation at all loads. The use of the potential transformer and voltmeter is prohibited in most cases by the cost of the instrument transformer and the excessive distorting load introduced by such an arrangement.

A voltmeter winding in the power transformer furnishes as a rule the most accurate and efficient method of measurement, the chief source of error being due to leakage flux and impedance drop in the transformer.

Connections for Test. — In Fig. 1 is shown the complete arrangement suggested by Hendricks for measurements of dielectric strength, energy loss in the dielectric and specific inductive capacity. The explanation of the figure follows: *A* exciter, *B* field switch, *C* generator field rheostat, preferably motor driven so as to vary voltage at constant rate, *D* main switch with auxiliary contact for lighting red lamp as a danger signal, *E* automatic circuit breaker, *F* series-paral-

lel switches on low-tension side of transformers, G ground connection, H instrument loop, I voltmeter winding with taps, J voltmeter, wattmeter and ammeter, K choke coils, L electrodes and M film cut-out.

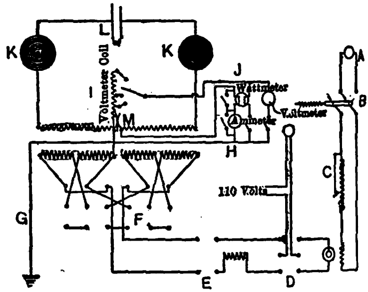

Fig. 1. Arrangement and Connections of Apparatus for High-tension Tests of Insulators

Causes of Variations in Results.—The puncturing voltage of an insulating material is affected by its previous history, precise condition when tested, size, thickness, form, uniformity of electrostatic field, temperature, time of electrification, frequency and the surrounding medium. The puncturing voltage is affected more by temperature than any other factor, and since the temperature of a specimen is increased greatly under the action of the corona discharge (*see Corona*) it is desirable that corona discharge should be eliminated. To prevent the heating action of the corona, 1. guard rings may be applied, as described by Ryan, Norris and Hoxie, 2. the electrodes may be imbedded in the dielectric when possible, 3. the "picein drop" method described by Walter may be used on the specimen, or 4. the electrodes and test specimen may be immersed in oil as recommended by Hendricks. In the last case materials easily permeated by oils should be glazed over with a varnish before testing. While the temperature of insulation in practice may range from − 25° C. to + 125° C., tests between + 25° C. and + 100° C. should suffice to indicate average working conditions.

SPECIFIC INDUCTIVE CAPACITY OR DIELECTRIC CONSTANTS. — (*See also Condensers.*) The specific inductive capacity of any substance is the ratio of the capacity of a condenser, in which the substance in question fills the space between the plates, to the capacity of the same condenser when the space between the plates is filled with air. This ratio, designated by K, varies with the temperature of the substance, the time of electrification used in the test and the frequency, when tested with alternating currents. The specific inductive capacity of most substances decreases as the temperature increases, except in the case of a few substances for which the specific inductive capacity increases with increased temperatures. The specific inductive capacity in general increases with the time of electrification and decreases as the frequency increases. The determination of the specific inductive capacity from test involves the determination of the capacity of a condenser of known dimensions. A plate or cylindrical condenser is commonly used for solid material and a spherical condenser for liquids. Having determined the capacity of any condenser of known dimensions from test, the specific inductive capacity of the dielectric used can be obtained by substituting the known constants in the condenser formulas given in the article on *Capacity and Charging Current*.

Direct-deflection Method. — The unknown condenser C_x and a ballistic galvanometer are connected in series with a battery of about 500 volts e.m.f. and the deflection D_x is noted. A standard condenser C_s is then substituted for the unknown condenser and capacity is inserted until the deflection D_s upon charging is the same as in the first case. Then

$$C_x = \frac{D_x}{D_s} C_s.$$

As most condensers possess leakage and absorption, the method gives erroneous results, since no distinction is made between charging current and leakage current. Zelleny gives a modification of this method in which, by regulating the time of charge, insulation and discharge, a constant deflection may be obtained.

Resonance Method. — The condenser and a variable inductance are connected in series in a circuit of high frequency and low resistance. A modification of this method is given by Rohman. Resonance is obtained and detected by noting the maximum value of the current as the inductance is varied. Then

$$C = \frac{1}{4\pi^2 f^2 L},$$

provided the effective conductance of the condenser is negligible and the impressed voltage is a pure sine wave.* The accuracy of this method depends principally upon the flexibility and precision of the variable inductance, upon the actual shape of the voltage wave and upon the leakage resistance of the condenser.

Alternating-current Bridge. — The unknown condenser C_x and the standard condenser C_s are connected in the arms of a Wheatstone bridge (q.v.) as shown in Fig. 2. The resistances R_1, R_2 and R_3 must be wound non-inductively. The detector D consists of a telephone receiver or a vibration galvanometer. After connecting the bridge to a high-frequency source of sinusoidal e.m.f., R_1, R_2 and R_3 are adjusted until a minimum current passes through the detector. Then, assuming the effective conductance of the dielectric to be negligible,

$$C_x = C_s \frac{R_2}{R_1}.$$

Sources of error are: inductance or capacity of R_1, R_2 and R_3, error in ratio of R_1 and R_2, and electrostatic induction between the bridge and its surroundings.

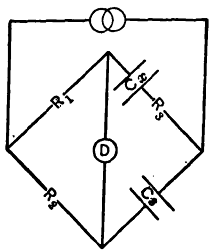

Fig. 2.

INSULATION RESISTANCE. — The method commonly employed is one of substitution. A standard resistance R_s (usually 1/10 megohm) connected in series with a D'Arsonval galvanometer is connected across a direct-current source of e.m.f. of about 500 volts and the deflection D_s of the galvanometer noted. The galvanometer must have a sensitiveness of about 1×10^9 and the deflection should be directly proportional to the current. If the galvanometer is shunted, an Ayrton universal shunt should be used (*see Shunts*) so that the damping of the galvanometer will be independent of the multiplying power. The deflection D_x is then noted when the unknown resistance R_x is connected in place of the standard resistance. Then

$$R_x = \frac{D_s}{D_x} R_s.$$

The usual errors of this method are due to leakage and absorption. Leakage may be reduced considerably by the use of a guard ring, so connected as to shunt the leakage current around the galvanometer. The deflection of the

* The exact formula for a sine-wave voltage is

$$2\pi f l = \frac{2\pi f C}{(2\pi f C)^2 + g^2},$$

where g is the effective leakage conductance (*see Alternating Currents*).

galvanometer will vary with time due to absorption, and the resistance of the material will apparently vary with the time of electrification. To facilitate comparison of the insulation resistance of dielectrics, it has become common practice to take the resistance obtained after one minute's electrification. Owing to the large negative resistivity temperature coefficient of most dielectrics, it is essential that the temperature of the material be noted when tested.

ENERGY LOSS IN THE DIELECTRIC — EFFECTIVE CONDUCTANCE. — If the transformer losses can be determined accurately under the testing conditions, the energy loss in the dielectric may be determined at any voltage by measuring the input to the transformer and then subtracting the transformer losses. Since the transformer losses are usually large compared with the dielectric losses, it is preferable to adopt the arrangement suggested by Hendricks, Fig. 1, and connect the wattmeter in the high-tension winding. The wattmeter then reads directly the dielectric losses at any voltage, the only error being that due to copper losses in the high-tension winding, which may be corrected for. The watts lost divided by the square of the voltage gives the effective conductance of the dielectric.

[R. G. Hudson.]

INSULATOR PINS. — (*See also Cross Arms; Insulators for Overhead Lines.*) Insulator pins are made of wood, iron and various combinations of wood, iron and porcelain.

WOODEN PINS. — Wooden pins are usually made of locust but sometimes of oak, birch, maple or eucalyptus.

The forest service reports: "Black locust is admitted to be the best of all woods used for insulator pins, but of late years other woods are being brought into use. Among those which will probably prove satisfactory as substitutes for the black locust are Osage orange, various oaks, yellow birch, gum, hard maple, elm, etc." Also: "The value of eucalyptus, particularly blue gum, for insulator pins has been thoroughly demonstrated. After fifteen years' service, sound pins are still in use."

Standard Distribution Pins (Fig. 1). — The standard wooden pin for distribution lines is of locust, 9 inches long, 1½-inch diameter shank, and 1 inch diameter thread, as shown in Fig. 1. It is often described simply as a "1½-in. by 9-in. pin." It is standard for use with double-petticoat deep-groove glass insulators and is also used for some insulators designed for higher voltages.

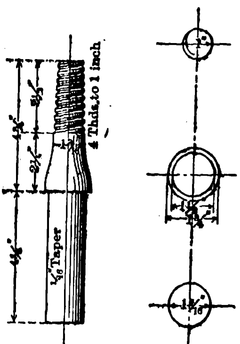

Fig. 1. Standard Locust Pin

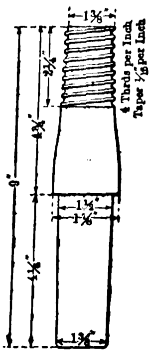

Fig. 2. Insulator Pin for 13,000 Volts

High-voltage Distribution Pins (Fig. 2). — For voltages above 2200 and not exceeding 13,200 it is desirable to have pins with 1½ inches diameter shanks to fit standard cross arms, but with larger threads, as shown in Fig. 2.

High-voltage Transmission Pins. — For voltages above 13,200 and not exceeding 25,000 wooden pins are used to a considerable extent. These pins are special and their length must be sufficient to give the clearance from insulator to cross arm required by the design of insulator used. The shanks should be larger than those of standard pins.

Paraffined Pins for High Voltage. — On high voltages wooden pins are too weak for the high stress which usually results from the great pin leverage of large insulators; such pins also rapidly deteriorate from a chemical action called "digestion," especially if insulators are too small for the voltage. Paraffined wooden pins have been used to reinforce the insulation in some cases where the insulators have been too small. Paraffined pins are useless as insulation unless the wood is first *thoroughly* dry and is then *thoroughly* impregnated. It is almost impossible to accomplish this in practice and the paraffining of commercial pins should be considered only as a preservative treatment.

Porcelain Bases for High-voltage Pins. — Porcelain bases are used to a small extent and for certain types of insulators. These extend from bottom of thread to top of arm. They are used for the purpose of preventing arc from striking pin when insulator arcs over. They act as a reinforcement of the insulation and may be used to assist an insulator which has inadequate insulation, due to incorrect design, or to enable it to be used on a higher voltage than intended. In general it is better to put all of the insulation in the insulator than to divide it between the insulator and the pin.

IRON DISTRIBUTION PINS. — Iron pins (malleable iron and drop-forged iron) are made with 1½-inch shanks and 1-inch threads so as to be interchangeable with standard wooden pins. They are used at points of heavy strain.

Pins with Iron Shanks consisting of ½-inch, ⅝-inch or ¾-inch iron bolts are also used. These have a nut and washer on the lower end used for pulling the base of the pin firmly into contact with the top of the arm. This type of pin has the advantage that the smaller hole removes less wood from the arm. For heavy stresses the shank of the pin should be stiff, or the base of the pin broad to prevent local crushing of wooden cross arms due to the pin leverage.

ATTACHMENT OF INSULATORS TO PINS. — Insulators are usually attached to wooden pins by a screw thread having a pitch of 4 threads per inch. The threaded portion of the pin is tapered, the diameter increasing downward from the top about 1/16 inch per inch of length. Standard thread diameters are 1 inch for distribution insulators and 1⅜ inches for high-tension insulators measured at the small end over the thread. Good fit in the thread between pins and insulators is not commonly attained because: (1) the threads are often imperfectly cut on the pins, (2) the wood of the pin shrinks so that it ceases to be circular or warps so that the axis of the pin is not truly straight, (3) the porcelain of the insulator warps in manufacture so that the hole ceases to be circular or the surface of the thread may not be smooth. Where a pin does not screw into the insulator to full depth intended, or where it is loose or bears unequally, the strength of the attachment is much reduced. The weakest point is usually at the root of the bottom thread.

Attachment of Insulators to Iron Pins. — Insulators are sometimes attached to iron pins by a screw thread similar to that used for wooden pins. The thread on the iron pin is often made of lead to get a more uniform bearing. High-tension insulators are frequently cemented to iron pins. The pin hole of the insulator may be threaded as usual. The end of the pin is usually corrugated or fluted instead of being threaded. The pin is grouted to insulator with neat Portland cement.

ATTACHMENT OF PINS TO ARMS. — The standard wooden distribution pin has a shank of 1½-inch nominal diameter. The actual diameter at the top is the same as the nominal diameter, the shank tapering so that the bottom is about 1/16 inch smaller. The pin hole in the cross arm is bored to the nominal diameter but often becomes smaller (across the grain) due to shrinkage of the wood, so that a standard pin, although smaller than nominal size of the pin hole except at extreme top, will often make a good driving fit. Pins which are too small (or pin holes which are too large) will make a loose fit and should not be used. Pins are often made considerably oversize at the top and undersize at the bottom to allow for inaccuracy of workmanship. Such pins will not drive completely in, and they weaken the construction by increasing the pin leverage and decreasing the bearing surface between the pin and cross arm. At the top of the shank a shoulder should be provided to limit the distance the pin can be driven in. For maximum strength the shank should be long enough to go completely through the arm and the taper should be small enough so that it will

bear against the arm for the full depth without leaning far to one side. The standard 1½-inch by 9-inch pin has a 4¼-inch shank length corresponding to the old "standard" depth of cross arm, and, therefore, does not develop the full strength of the later standard arms which are 4½ inches or 4¾ inches deep.

Pins are prevented from pulling out of the arm (especially where the wire exerts an uplift on the insulator and pin) by driving a nail (usually six-penny) through arm and pin.

Wooden pins for high-tension insulators are made with larger diameter shanks, 2 inch, 2¼ inch and 2½ inch being used.

Comparative Strength of Some Special High-tension Pins.—The following are the results of tests made on pins fitted into wooden cross arms. The pins broke at the top of the shank.

Material	Dimensions of shank, inches		Pin leverage, inches from center of stress to top of arm	Breaking strength, pounds
	Diameter	Length		
Oak	2¼	6	12	140
Oak	2¼	6	16	120
Oak	2½	6	12	205
Oak	2½	6	16	120
Eucalyptus	2¼	6	about 10	260
Red oak	2½	7¼	12½	495
White oak	2½	7¼	12½	738
Locust	2½	7¼	12½	1121

COSTS.—The following figures, giving the cost, are rough approximations.

Material	Dimensions in inches			Approximate cost per 1000
	Diam., Shank	Overall length	Diam., Top	
Standard Oak (Fig. 1)	1½	9	1	$ 7.50
Standard Locust (Fig. 1)	1½	9	1	14.00
Special Locust	1½	10¾	1⅜	22.00
Solid Drop-forged Galvanized Iron	1½	9	1⅜	500.00

[R. A. PHILIP AND CABOT STEVENS.]

INSULATORS FOR OVERHEAD LINES. — (*See also Distribution Lines; Insulator Pins; Transmission Lines.*) Insulators for overhead lines may be classified as insulators for distribution lines, pin insulators for transmission lines and suspension insulators for transmission lines. The general features of design common to all classes of line insulators will first be considered.

DESIGN OF LINE INSULATORS. — Glass is commonly used for making small low-voltage insulators and porcelain for large insulators. Porcelain has greater mechanical strength, condenses less moisture on its surface and parts may be cemented together, but faults cannot be as readily detected as in glass. Glass insulators are often completely shattered by a blow while porcelain insulators usually are only chipped under similar circumstances. Various compositions are also used to a limited extent for line insulators.

Properties of Porcelain and Glass. — Following are some of the more important characteristics of porcelain and glass:

Property	Glass	Porcelain
Tensile strength, lb. per sq. in.	2,500–9,000	1,500–2,200
Crushing strength, lb. per sq. in.	6,000–10,000	14,000–16,000
Elastic limit, lb. per sq. in.	3,200 approx.	....
Modulus of elasticity, lbs. per sq. in.	8,000,000	2,500,000 (*b*)
Coeff. of expansion per °F.	0.0000046	0.00000585 (*b*)
Coeff. of expansion per °C.	....	0.00000413 (*a*)
Weight per cubic foot in lbs.	160	155
Puncturing strength in volts per inch	300,000	400,000
Specific inductive capacity (air = 1)	5 to 10 (*a*)	4.38 (*a*)

(*a*) Smithsonian Physical Tables. (*b*) Austin, A. O., *Proc. N.E.L.A.*, 1913.

In American practice porcelain parts are made from ¼ inch to ⅝ inch in thickness. In European practice porcelain is used in thicknesses up to 1 inch. The working voltage usually averages from 10,000 to 20,000 volts for each thickness of porcelain used. 15,000 volts is about an average figure, so that a 30,000-volt insulator usually has two parts, a 40,000-volt insulator 3 parts and a 60,000-volt insulator 4 parts.

Requirements to be Met in a Satisfactory Design. — Shapes that are very long or very large in diameter are not economical to manufacture. The design of high-tension insulators is a "cut and try" process and many of the principles have not yet been reduced to a scientific basis. An insulator must be designed to stand extreme and sudden temperature changes, sleet and rain as well as smoke, dust and sometimes special conditions such as salt storms and salt-water spray without deterioration from chemical action, breakage from mechanical strain or electrical failure.

Some of the principal points in the electrical design of high-voltage insulators are:

Thickness to Resist Puncture. — The porcelain must be thick enough to resist puncture. If this thickness is greater than is desirable from a manufacturing standpoint, two or more pieces are used to give the proper aggregate thickness.

Arcing Distance; Free Arcing. — The porcelain must extend beyond the charged conducting connections (i.e., tie wire or cap at the top and pin at

the bottom) sufficiently so that the distance between the connections through the air around the porcelain is greater than the arcing distance of the maximum voltage to be carried. The arcing distance required for a given voltage may be determined roughly (but only very roughly) from the tables of arcing distances between needle points; see article on *Spark Gap*. The greater radius of curvature (compared with needle points) of such metal parts as the insulator pin decreases the potential gradient at the terminals. Also the porcelain has a much greater specific inductive capacity than the air and its proximity to the arcing path disturbs the electrostatic field through the air. Surface charges on the porcelain because of surface leakage or corona also modify the field.

Free arcing is the property of arcing over along a line which does not touch the porcelain body from the point where the arc leaves the metal cap to where it strikes the metal pin. Where the arc touches any part of the porcelain the great heat fractures the porcelain in a few seconds; hence the desirability of designing the insulator so that it is free arcing. A properly designed insulator will arc over as a whole before any individual part (i.e., shell or unit) arcs over. In many defective designs the insulator will fail by some parts arcing over, thereby increasing the voltage on others which then fail by puncture or arcing over.

Factor of Safety Against Puncture. — The thickness of a porcelain part must be so related to the distance around it that it will arc over before it will puncture. The ratio of puncture strength to arc over voltage is the factor of safety of the part, or of the insulator, against puncture.

Guard Rings and Rods. — Where an insulator is not naturally "free arcing" from cap to pin, properly located rings or rods will divert the arc so as to accomplish an equivalent result. Rings used for this purpose are known as Nicholson guard rings. Where a pin insulator is improperly designed so that it is liable to puncture before flashing over, a Nicholson ring around the base may be used to redistribute the potential or to reduce the arcing distance so as to reduce trouble from puncture. Such rings and rods are also sometimes used in connection with suspension insulators.

Rated voltage	Length of leakage surface, inches
5,000	4
6,600	5½
10,000	6¾
23,000	12
44,000	29
66,000	53

Leakage Surface. — Leakage surface is ordinarily measured as the number of (linear) inches from cap (or equivalent) to pin taken radially along the surface; see Fig. 3. This, however, is only a rough measure as it neglects the varying width of leakage path. The figures in the accompanying table on pin insulators from a manufacturers' catalog give approximately the total amount of leakage surface used in practice. The amount of surface allowed varies considerably between different designs and makes.

Spread of Petticoats of Pin Insulators. — In two concentric shells the two surfaces which lie opposite to each other are at different potentials except where they are cemented together. The difference in potential between two points on opposite surfaces is greater the further they are removed from the joint. Unless the shells diverge correspondingly so as to increase the distance between the shells as the potential increases the air will break down and part of the leakage surface will be short-circuited by a corona discharge. This divergence is shown in Fig. 3, where the top is a disc made slightly con-

vex to shed water and the inner shells are a series of cones which radiate from the top of the pin.

Color and Glazing. — Brown, slate and white are the common colors used in glazing porcelain. Brown is the most common color since it is more of an aid in determining faults. Slate colored glazing of the same color as galvanizing on towers makes insulators a less conspicuous target for malicious destruction.

Cementing of Insulators. — Insulator parts are cemented together with neat freshly burned and finely-ground Portland cement which is usually allowed to set under water from ten to fourteen days before testing mechanically. The more freshly burned and finely ground the cement and the higher the temperature, the less time required for setting. The cemented surfaces of porcelain are unglazed and corrugated to obtain good bond.

Faults in Insulators. — The more common faults in porcelain are folds and flaws in moulding and the development of checks and hair cracks in process of drying, incomplete and non-uniform glazing, warping, air bubbles, conducting impurities, under- and over-firing and chipping of edges. Only 50 to 75 per cent of moulded shapes ordinarily pass final test and even a less number of the more difficult shapes. Inspection and testing are essential to eliminate faults in both design and manufacture.

DISTRIBUTION-LINE INSULATORS, STANDARD (Fig. 1). — For ordinary distribution circuits, including constant-potential circuits up to 2200 volts nominal and series-arc circuits of all voltages, the double-petticoat deep-groove (D.P.D.G.) insulator, of the type shown in Fig. 1, is standard.* Such insulators are usually of glass, though occasionally of porcelain, and in cases where there are heavy stresses, as at dead ends where iron pins are required, the insulators are made of moulded mica. The dimensions vary with different manufacturers.

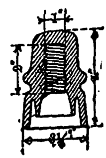

Fig. 1.

These insulators are used with the standard pin shown in Fig. 1 in the article on *Insulator Pins*.

Pony Insulators. — These are small insulators used for telegraph and telephone wires. They are unsuitable for electric light and power wires. The groove is too small (sometimes only ¼ in.) to properly support the larger wires used for lighting and the leakage surface is insufficient for proper insulation.

Insulators with Top Groove. — The standard distribution insulator has a groove in the side to which the wire is tied. For very heavy cables special insulators with groove in top are used. Insulators for higher voltage usually have both side and top groove, the former used where there is horizontal stress due to angle in line, and the latter on straight parts of line where the weight is the principal force.

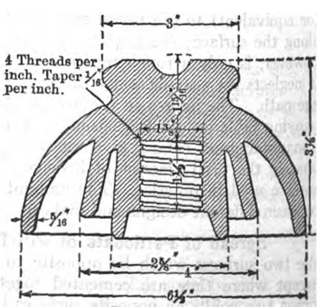

Fig. 2.

DISTRIBUTION-LINE INSULATORS, HIGH-VOLTAGE (Fig. 2). — For circuits exceeding 2200 volts

* The same size insulator is used for 110-volt and 2200-volt circuit. This has the advantage that only one kind of insulator is kept in stock, and a wire can be transferred from use on a low-voltage circuit to one of higher voltage without reinsulating it.

but not exceeding 13,200 volts nominal, it is convenient to have insulators which can be used on the standard distribution pins. A number of insulators are made with 1-in. threads to fit the standard 1½-in. by 9-in. pin. It is better, however, to use stronger special pins with 1⅜-in. top; see article on *Insulator Pins*. Fig. 2 shows an insulator which has been used on these voltages. It is used with the pin shown in Fig. 2 in the article on *Insulator Pins*. The manufacturer rates this insulator at 23,000 volts with a factor of safety (wet) of 2.

TRANSMISSION-LINE INSULATORS, PIN-TYPE (Fig. 3).—The pin-type insulators are similar in mechanical construction to the low-voltage insulators used for distribution lines, but are larger and designed for heavier mechanical stresses as well as higher voltages. The conductor is supported on a top groove except where an angle in the line causes a lateral pressure, in which case the side groove is used. For voltages up to about 10,000 volts the insulator usually consists of but a single porcelain part. For higher voltages from two to five parts are cemented together. The size and expense of pin-type insulators increase rapidly with the voltage so that while they may be used for operating potentials of 70,000 and even more, their use is generally restricted to potentials of not over 50,000. A typical three-part insulator is shown in Fig. 3. The separate parts are called parts, shells or cones and are numbered in order beginning with the top.

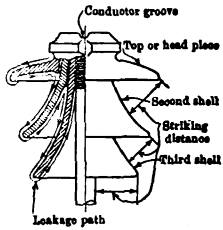

Fig. 3.

Tie Wires and Clamps.—Tie wires consisting of the same material as conductors are commonly used for fastening conductor to insulator. Two common types of ties are shown in Figs. 4 (single tie wire) and 5 (double tie

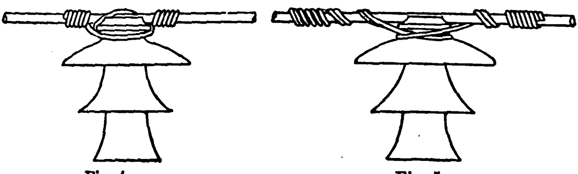

Fig. 4. Fig. 5.

wire). For copper conductors the tie wires are usually soft-copper wires which are three sizes on the A.W.G. (B. & S. gage) smaller than the conductor. Metal caps carrying clamps for conductor are cemented to tops of insulators when more strength is required than can be obtained by tie wires.

TRANSMISSION-LINE INSULATORS, SUSPENSION TYPE (Figs. 6 to 8).—The suspension-type insulator is always used in tension, the connections at the two ends being made so that the insulator is free to swing in any direction; the insulator takes such a position that its axis coincides with the direction of the mechanical stress. This type is used hanging below the cross arm with axis vertical as a suspension insulator for sustaining the weight of cable at points where there is little horizontal force, and also with axis approximately horizontal as a "strain" or "dead-end" insulator at points where the horizontal force predominates.

The suspension type consists of one or more complete insulators, called "units," connected in a string. Each unit consists of one or more insulating

parts usually with a metal cap above and a metal pin below, all cemented together. Typical designs of suspension units are shown in Figs. 6 to 8.

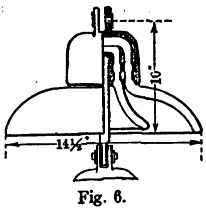

Fig. 6.

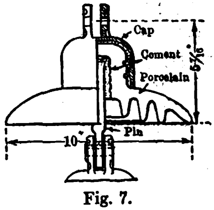

Fig. 7.

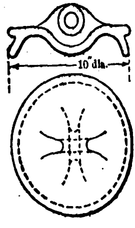

Fig. 8.

Relation Between Electrical Strength of Single Unit and a String of Units.—The potential per unit required to flash-over suspension insulator composed of units of the same design decreases with an increasing number of units as shown in Fig. 9. This is probably due to an unequal potential gradient.

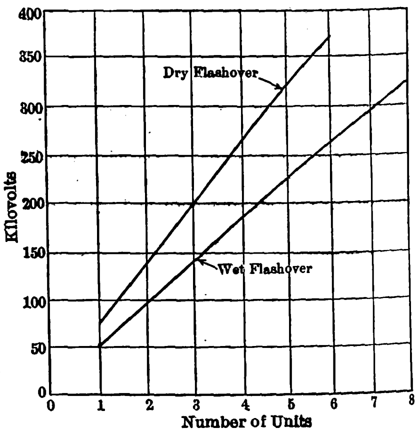

Fig. 9.

Connections Between Suspension Units.—The caps and pins of suspension insulators are commonly made of galvanized malleable iron castings, but where strength is required the pins are steel drop forgings. The common types of connection between the pin of one insulator and the cap of the one next below are ball and socket, clevis and pin (Figs. 6 and 7) and hook and eye. The hook and eye is the simplest type, but there is danger of its becoming unhooked and, in order to obtain strength, the design requires more space between units than other types of connection. The clevis and pin has the disadvantage of loose parts. The ball-and-socket connection requires special terminal fittings and a rigid connection to prevent the clamp from turning when used on dead-end insulators for conductors which tend to untwist. It can, however, be designed with less space between units than other types.

A type of suspension insulator which does not require caps and pins is shown in Fig. 8. These units are connected together by cable loops. This was one of the first types of suspension insulators. It is not commonly used on account of cost of manufacturing. The holes for cables require filling with cement or other material to prevent the insulators breaking by the collection and freezing of water in them in cold climates. A very close inspection is often required to find punctured units that are not shattered by the failure.

Conductor Clamps for Suspension Insulators. — A common form of insulator clamp is shown in Fig. 8 in the article on *Wires and Cables, Bare*. These clamps are commonly made of malleable iron castings. Fig. 10 shows a pressed steel clamp designed for and used on the Keokuk-St. Louis transmission line. This clamp is used on both suspension and "dead-end" or strain insulators. Clamps should have an ultimate holding power of not less than 50 per cent in excess of the elastic limit of the cable for which they are used.

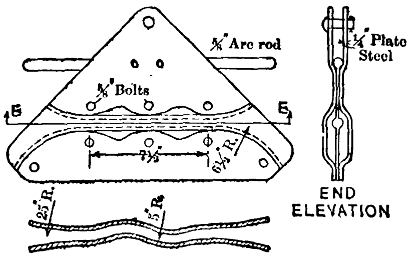

Fig. 10.

TESTS OF INSULATORS. — Tests of insulators may be classified as (1) design tests, made on a very few insulators to determine the characteristics of new designs, and (2) routine tests made on each insulator manufactured to detect defects of material or workmanship.

Design Tests. — Design tests are quite expensive for very high-voltage insulators because of the difficulty of securing suitable testing apparatus.

Mechanical Tests should be made to determine the strength. With pin-type insulators the important point is the strength of pin and insulator combined against a force (representing a horizontal wire pull) applied at the wire groove in a direction at right angles to the axis of the pin. For suspension-type insulators the tensile strength is the important mechanical consideration. These tests should be carried to the point of destruction of a number of samples.

Electrical Tests should be made for puncture strength, arc-over voltage dry and wet, free arcing properties and corona formation. The electrodes used should conform in shape to the cap and pin used in practice so that all surface exposed to puncture when the insulator is in use will be tested. Design tests of the electrical properties of suspension insulators should be made on complete strings of insulators as well as on single units.

Puncture Test. — As the air surrounding a properly designed insulator acts as a safety valve, it is necessary to immerse the insulator in oil in order to test the material of which the insulator is composed up to its puncture strength at normal frequency. Such a test may be used to ascertain the margin by which the puncture strength exceeds the flash-over voltage and to verify the dielectric strength of the porcelain. High frequencies are found to produce puncture in air in insulators which arc over before they puncture at normal operating frequencies. Standard methods of using high frequencies as a means of testing have not been developed. The frequencies used for normal tests include all commercial frequencies or say from 25 to 125 cycles per second with 60 cycles the most common.

Arcing Tests. — Arcing tests, both dry and wet, are made to determine the voltage at which an insulator will arc over when the voltage is raised with the insulator in its normally dry condition and when wet as in rainy weather. The dry arcing test is the most common one made because of its simplicity, the voltage merely being raised on cap and pin until arc over occurs. Wet test in new designs is very important as there is danger of puncture or arc over of individual parts which appear safe on dry test. The standard precipitation

for a wet test is 1/5 inch of distilled water per minute inclined at an angle of 45° with the axis of the insulator. The wet arcing test usually gives a lower arc-over voltage and hence gives a measure of the electrical factor of safety of the line (ratio of voltage at which failure occurs to working voltage) under the weather conditions when the factor is usually the lowest.

Free Arcing Tests. — In order to test the free-arcing properties the testing transformer must be large enough so that the flash at time of arc over will continue as a true power arc; even then the phenomena of fracture will rarely occur, even if the insulator is not free-arcing, because of the comparative feebleness of the power used in testing.

Corona Formation is indicated by the emission of a sound (i.e., the insulator is not "quiet") and may be still more accurately detected by the light from the corona when insulator is tested in the dark. Corona is considered an evidence of defective design and it is considered desirable that the voltage of corona formation should not be much below the arc-over voltage and certainly not below working voltage. However, many and perhaps most, high-voltage insulators show some corona at working voltage, though the amount is so small that it is difficult to detect.

Routine Tests. — No high-voltage insulator should be used without having been tested at the factory. Mechanical tests, except on a few selected samples, are not ordinarily made on pin-type insulators. On suspension insulators a tension test on each unit is desirable, but should not exceed about one-half the expected ultimate strength, for this is sufficient to eliminate defective ones, and an insulator is permanently injured at a point somewhat below its ultimate strength.

Flash-over or arcing tests should be made on each porcelain part before assembly (so that no poor part will get into any insulator) and on the whole insulator when assembled. Each part should be tested to flash-over potential for five minutes. The cup-shaped parts (also complete pin-type insulators) may be tested by setting them inverted in a pan of water used as one electrode, and partly filling the cup with water for the other. A large number of similar parts are ordinarily tested simultaneously in this way. Assembled suspension units are tested by using pin and cap as electrodes. The string of units forming a complete suspension insulator is not tested, except for a few selected samples (design tests). Factory tests of parts can be made at the factory with a transformer which will give a moderately high voltage, and no special measuring instruments are necessary, as the fact that parts are tested to arc-over voltage is evidenced by the fact that the arc-over is visible.

SPECIFICATIONS FOR INSULATORS. — (*See also article on Specifications.*) Several specifications for high-voltage insulators have recently been suggested as suitable for "Standard Specifications"; see papers by Peek, Sanford and Thomas in *Transactions of A.I.E.E.*, July, 1913. Specifications covering the inspection and tests of porcelain high-tension line insulators for over 25,000 volts, which had been prepared by the High Tension Transmission Committee of the A.I.E.E., were presented at the 1914 annual convention of the Institute. The reader is referred to the above-mentioned papers for details.

INSTALLATION OF INSULATORS. — See the articles on *Distribution Lines* and *Transmission Lines*.

WEIGHTS AND COSTS. — The approximate dimensions, weights and costs of glass and porcelain pin-type insulators and for porcelain suspension units for different operating and test voltages are as follows:

PIN TYPE

Material	Operating voltage, volts	Test voltage		Diameter, inches	Height, inches	Number of parts	Weight, pounds	Cost, dollars
		Wet, volts	Dry, volts					
Glass.......	110-2,200	......	......	3¼	4	1	1¼	0.03
Porcelain...	13,200	40,000	80,000	6½	3¾	2	3⅜	0.18
Porcelain...	22,000	45,000	72,000	7	5	2	5	0.50
Porcelain...	33,000	60,000	90,000	9	8	2 or 3	8	0.75
Porcelain...	44,000	80,000	110,000	10½	10	3	13	1.20
Porcelain...	50,000	95,000	120,000	12	11	3	18	1.50
Porcelain...	60,000	115,000	150,000	14	13	4	27	2.00

SUSPENSION TYPE UNITS

Diameter, inches	Number of parts	Spacing, inches	Test voltage		Ultimate strength, pounds	Working stress, pounds	Weight, pounds	Cost, dollars
			Wet, volts	Dry, volts				
10	1	5½	50,000	75,000	8,000	4,000	11	1.00
12	1	6½	50,000	75,000	9,000	4,500	13	1.40
14	2	9	65,000	90,000	12,000	6,000	20	2.00

[R. A. PHILIP, CABOT STEVENS and E. A. EKERN.]

INTEGRALS. — (*See also Derivatives; Equations, Differential.*) If the function $y = f(x)$ be plotted as a curve (see Fig. 1) and the axis of x be divided into a number of very small sections, each of width dx, the area between the curve and the axis of x may be conceived as the sum of the products obtained by multiplying each length dx by the corresponding altitude or ordinate y. Then

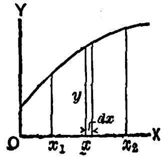

Fig. 1.

$$\text{Area} = \int y\,dx,$$

where $\int$ stands for "sum."

The Definite Integral. — The area between the values x_1 and x_2 is written

$$\int_{x_1}^{x_2} y\,dx.$$

Such an expression is called a "definite integral."

It is evident from the figure that the area of the curve between x_1 and x_2 is equal to the difference between the area from o to x_2 and the area from o to x_1. Hence calling the former area $F(x_2)$ and the latter area $F(x_1)$, we have

$$\int_{x_1}^{x_2} y \cdot dx = F(x_2) - F(x_1).$$

This equation is the general expression for any definite integral.

Indefinite Integrals. — The above equation may also be written

$$F(x_2) = \int_{x_1}^{x_2} y\,dx + F(x_1)$$

and if x_2 is considered a variable, the subscripts are omitted, as follows:

$$F(x) = \int y\,dx + A,$$

where A is a constant for any given reference point x_1. This constant A is an arbitrary constant, since any point x_1 may be chosen as the reference point, but when a point is once chosen, A is fixed. The expression $\int y\,dx$ is called an "indefinite integral" and A is called the "integration constant."

From the definition of a derivative (*see Derivatives*), the derivative of $F(x)$ is

$$\frac{dF(x)}{dx} = \frac{\int_{x_1}^{x+dx} y dx - \int_{x_1}^{x} y\,dx}{dx}$$

and from the figure, it is evident that the difference between the area from x_1 to $x + dx$ and the area from x_1 to x is simply $y\,dx$. Hence

$$\frac{dF(x)}{dx} = y,$$

that is, the integral $F(x)$ of any function y, with respect to x, must be such a function that when differentiated with respect to x, the result is the function y.

Formulas for Integration. — u, v, x and z are variables; a, m and n are constants.

$$\int (u+v)\,dx = \int u\,dx + \int v\,dx$$

$$\int y\,dx = \int y\,\frac{dx}{dz}\,dz$$

$$\int u\,dv = uv - \int v\,du$$

$$\int \frac{F'(x)}{F(x)} = \log F(x)$$

where $F'(x)$ stands for $\dfrac{dF(x)}{dx}$.

TABLE OF INTEGRALS

Function $f(x)$	Integral $\int f(x)dx$	Function $f(x)$	Integral $\int f(x)dx$
x^m	$\frac{1}{m+1}x^{m+1}$	$\frac{1}{\sqrt{a^2-b^2x^2}}$	$\frac{1}{b}\sin^{-1}\frac{b}{a}x$
$\frac{1}{ax}$	$\frac{1}{a}\log_\epsilon ax$	$\frac{1}{\sqrt{a^2+b^2x^2}}$	$\frac{1}{b}\sinh^{-1}\frac{b}{a}x$
ϵ^{ax}	$\frac{1}{a}\epsilon^{ax}$	$\frac{1}{a^2+b^2x^2}$	$\frac{1}{ab}\tan^{-1}\frac{bx}{a}$
a^{bx}	$\frac{1}{b\log a}a^{bx}$	$\frac{1}{(a^2-b^2x^2)_{bx<a}}$	$\frac{1}{ab}\tanh^{-1}\frac{bx}{a}$
$\cos ax$	$\frac{1}{a}\sin ax$	$\frac{1}{(a^2-b^2x^2)_{bx>a}}$	$\frac{1}{ab}\tanh^{-1}\frac{a}{bx}$
$\sin ax$	$-\frac{1}{a}\cos ax$	$\frac{1}{(x-a)(x-b)}$	$\frac{1}{a-b}\log\frac{x-a}{x-b}$
$\tan ax$	$-\frac{1}{a}\log(\cos ax)$	$\frac{1}{\sqrt{2ax-x^2}}$	$2\sin^{-1}\sqrt{\frac{x}{2a}}$
$\cosh ax$	$\frac{1}{a}\sinh ax$	$\frac{1}{x\sqrt{x^2-a^2}}$	$-\frac{1}{a}\sin^{-1}\frac{a}{x}$
$\sinh ax$	$\frac{1}{a}\cosh ax$	$\frac{1}{x\sqrt{x^2-a^2}}$	$\frac{1}{a}\cos^{-1}\frac{a}{x}$
$\tanh ax$	$\frac{1}{a}\log(\cosh ax)$	$\frac{1}{x\sqrt{a^2+x^2}}$	$-\frac{1}{a}\sinh^{-1}\frac{a}{x}$
$\tan x\sec x$	$\sec x$	$\frac{1}{x\sqrt{a^2-x^2}}$	$-\frac{1}{a}\cosh^{-1}\frac{a}{x}$
$\sec^2 ax$	$\frac{1}{a}\tan ax$	$\frac{x}{\sqrt{a^2\pm x^2}}$	$\pm\sqrt{a^2\pm x^2}$
$\frac{1}{\cos^2 ax}$	$\frac{1}{a}\tan ax$	$\frac{x}{\sqrt{x^2-a^2}}$	$\sqrt{x^2-a^2}$
$\frac{1}{\sin^2 ax}$	$-\frac{1}{a}\cot ax$		

Function $f(x)$	Integral $\int f(x)dx$
$\sqrt{a^2-x^2}$	$\frac{1}{2}\left(x\sqrt{a^2-x^2}+a^2\sin^{-1}\frac{x}{a}\right)$
$\sqrt{x^2+a^2}$	$\frac{1}{2}\left[x\sqrt{x^2+a^2}+a^2\sinh^{-1}\frac{x}{a}\right]$
$\sqrt{x^2-a^2}$	$\frac{1}{2}\left[x\sqrt{x^2-a^2}-a^2\cosh^{-1}\frac{x}{a}\right]$
$\sin ax \sin bx$	$\frac{\sin(a-b)x}{2(a-b)}-\frac{\sin(a+b)x}{2(a+b)}$
$\cos ax \cos bx$	$\frac{\sin(a-b)x}{2(a-b)}+\frac{\sin(a+b)x}{2(a+b)}$
$\sin^2 ax$	$\frac{1}{2}x-\frac{1}{4a}\sin 2ax$
$\cos^2 ax$	$\frac{1}{2}x+\frac{1}{4a}\sin 2ax$
$\sinh ax \sinh bx$	$\frac{\sinh(a-b)x}{2(a-b)}-\frac{\sinh(a+b)x}{2(a+b)}$
$\cosh ax \cosh bx$	$\frac{\sinh(a-b)x}{2(a-b)}+\frac{\sinh(a+b)x}{2(a+b)}$
$\sinh^2 ax$	$\frac{1}{2}x-\frac{1}{4a}\sinh 2ax$
$\cosh^2 ax$	$\frac{1}{2}x+\frac{1}{4a}\sinh 2ax$
$\epsilon^{ax}\sin bx$	$\frac{\epsilon^{ax}(a\sin bx-b\cos bx)}{a^2+b^2}$
$\epsilon^{ax}\cos bx$	$\frac{\epsilon^{ax}(a\cos bx+b\sin bx)}{a^2+b^2}$
$\frac{\epsilon^{mx}}{x}$	$\log_\epsilon x+\frac{mx}{1}+\frac{m^2x^2}{2!}+\frac{m^3x^3}{3!}+\text{etc.}$
$\sin^m x\cos^n x$	$-\int \sin^{m-1}\cos^n x\, d\cos x$

Double Integrals. — Just as the area of a surface may be represented by the expression

$$\int y \cdot dx$$

so the volume of a solid may be represented by

$$\int\left[\int y \cdot dx\right]dz$$

or adopting the usual notation, by

$$\int\int y\, dx \cdot dz$$

taken between limits determined by the data of the problem.

[W. A. Del Mar.]

INTEREST, ANNUITIES AND SINKING FUND. — Let

P = principal invested in dollars;
n = number of years principal is invested;
r = rate of interest, per cent per annum;
A = total amount of principal and interest at end of n years.

Note. — The following relations hold irrespective of the unit of time selected, provided r is taken as the interest earned per $100 during that time.

Simple Interest. — If the principal is invested at simple interest, then

$$A = \left(1 + \frac{nr}{100}\right)P.$$

Compound Interest. — If the principal is invested at compound interest, i.e., if the interest earned each year is invested at the end of that year at the same rate as the original principal, then the total amount due at the end of n years is

$$A = PR^n,$$

where

$$R = 1 + \frac{r}{100}.$$

R^n is the amount of the principal of 1 dollar and interest at the end of n years. The following table gives the value of R^n for n ranging from 1 to 50 years and r from 3 to 6 per cent.

VALUES OF $R^n = \left(1 + \frac{r}{100}\right)^n$

Years n	Per cent interest = r				Years n	Per cent interest = r			
	3	4	5	6		3	4	5	6
1	1.03	1.04	1.05	1.06	16	1.6047	1.8730	2.1829	2.5403
2	1.0609	1.0816	1.1025	1.1236	17	1.6528	1.9479	2.2920	2.6928
3	1.0927	1.1249	1.1576	1.1910	18	1.7024	2.0258	2.4066	2.8543
4	1.1255	1.1699	1.2155	1.2625	19	1.7535	2.1068	2.5269	3.0256
5	1.1593	1.2166	1.2763	1.3382	20	1.8061	2.1911	2.6533	3.2071
6	1.1941	1.2653	1.3401	1.4185	21	1.8603	2.2787	2.7859	3.3995

11	1.3842	1.5394	1.7103	1.8983	30	2.4272	3.2433	4.3219	5.7435
12	1.4258	1.6010	1.7958	2.0122	35	2.8138	3.9460	5.5159	7.6862
13	1.4685	1.6651	1.8856	2.1329	40	3.2620	4.8009	7.0398	10.2858
14	1.5126	1.7317	1.9799	2.2609	45	3.7815	5.8410	8.9847	13.7648
15	1.5580	1.8009	2.0789	2.3965	50	4.3838	7.1064	11.4670	18.4204

The following table gives the number of years required for a given principal to double itself at compound interest.

Interest Rate	3	4	5	6
Years to Double	23.5	17.7	14.2	11.9

Annuities. — An annuity is a fixed sum of money paid yearly, or at other equal times agreed upon.

One dollar invested at interest at r per cent at the beginning of every year will at the end of n years amount to

$$R \cdot \frac{R^n - 1}{R - 1} \text{ dollars,}$$

where $R = 1 + r/100$, the interest being compounded at the end of each year.

One dollar invested at the beginning of a period of n years will yield at the end of each year an annuity of

$$\frac{R^n (R - 1)}{R^n - 1} \text{ dollars,}$$

where $R = 1 + r/100$, the interest being compounded at the end of each year.

Sinking Fund. — A sinking fund is a fund built up from fixed yearly payments or annuities. Sinking funds are usually provided to retire bonds, which are issued for a given number of years. The annuity required to retire a bond of $1000 at the end of n years is

$$1000 \left(\frac{R - 1}{R^n - 1} \right).$$

Values of this annuity for various rates of interest and for various values of n are given in the following table.

ANNUITY REQUIRED TO REDEEM $1000

At end of years	Rate of interest, per cent								
	2	2½	3	3½	4	4½	5	5½	6
2	495.05	493.78	492.69	491.42	490.20	489.00	487.80	486.62	485.43
3	326.72	325.14	323.56	321.94	320.36	318.77	317.21	315.63	314.10
4	242.63	240.84	239.02	237.26	235.50	233.74	232.01	230.29	228.60
5	192.16	190.24	188.35	186.49	184.63	182.79	180.98	179.13	177.39
6	158.53	156.56	154.61	152.67	150.79	148.88	147.02	145.18	143.36
7	134.52	132.49	130.51	128.57	126.61	124.67	122.82	120.96	119.13
8	116.51	114.47	112.46	110.48	108.53	106.60	104.72	102.86	101.03
9	102.52	100.46	98.44	96.44	94.49	92.57	90.69	88.83	87.02
10	91.33	89.25	87.24	85.24	83.29	81.38	79.50	77.67	75.87

[W. A. Del Mar.]

IRON, PIG AND CAST. — (*See also Iron, Wrought; Castings, Iron and Steel; Magnetic Properties of Iron; Steel.*) Chemically pure iron is not a commercial product. Iron of a very high degree of purity may be obtained, however, by electrolytic deposition. The microscopical constituent of pure iron is called ferrite, and pure iron is said by metallographists to be composed of polyhedral crystalline grains of ferrite. Commercial products are pig iron, cast iron, malleable cast iron, wrought iron and steel.

PIG IRON. — Pig iron is the crude product obtained from iron ore by smelting in a blast furnace. The name is applied either to the molten material or to rough castings varying in length from 30 inches to 36 inches and in cross-section from about 10 sq. in. to 30 sq. in. A mass of piled pig iron 8 by 10 by 12 ft. weighs approximately 100 tons. Pig iron is made by burning a mixture of iron ore, coke or other fuel and limestone in a high furnace through which a blast of heated air is forced under pressure. The liquid iron when drawn from the furnace is either run into sand molds formed on the ground near the furnace, or into cast-iron molds forming a part of a conveyor chain which receives the molten iron, chills it by contact, and delivers it at the car. A pig is the bar of iron formed in either of these types of molds. The molten iron is also occasionally conveyed to the steel furnace without being allowed to cool.

Classification. — Pig iron may be classified as follows:

a. Gray, white or mottled as determined by the color of its fracture and its chemical composition.

b. Coke, anthracite or charcoal iron as determined by the fuel used in reducing the ore.

c. Foundry iron, Bessemer iron, etc., according to the use to which it is to be put.

Use of Pig Iron. — The product of the blast furnace is irregular in composition and physical properties and is not used directly. By forming it into pigs it is possible to grade it, and also transport it to foundries and iron and steel furnaces. Pig iron is sometimes used by engineers because of its great weight to form counterweights in unbalanced structures such as movable bridges, but concrete is more economical for this purpose.

Strength. — See below in the section on *Cast Iron*.

Specifications for Pig Iron. — See Standard Specifications for Foundry Pig Iron in Year Book of American Society for Testing Materials.

Cost. — The cost of pig iron is an important factor in commerce. Quotations are given weekly in *The Iron Age* and in the first issue of each month of the *Engineering News*. The fluctuations in price are very considerable, Bessemer pig at Pittsburg varying during 1912 from $14.90 to $18.15 per long ton of 2240 pounds.

CAST IRON. — Cast iron may be defined as iron containing so much carbon that it is not malleable at any temperature, specifically, iron cast into articles of specific form and purpose as distinguished from pig iron. Except for special cases castings are made of gray iron. Cast iron is made from pig iron by melting the latter and casting in sand or iron (chill) molds. The furnace commonly used is a cupola furnace although reverberatory furnaces are sometimes employed.

Composition of Cast Iron. — The composition of an iron casting is identical with that of the pig iron from which it is made and usually consists of metallic iron (ferrite) accompanied by from 2.5 per cent to 4 per cent (by weight) of carbon, together with silicon, phosphorus, manganese and other impurities.

The carbon may be chemically combined with the iron, giving homogeneous white iron, or some of it may be precipitated in cooling in the form of graphite, making gray iron or mottled iron. The influence of carbon upon the properties of the cast iron is of great importance and may be summed up as follows:

Uncombined Carbon or Graphite. — Porosity and workability increase and shrinkage decreases, with an increase in the percentage of graphite. Strength also generally decreases with an increase in graphite, although it should be noted that an iron may be weak by having too much combined carbon and that treatment which changes some of this combined carbon to graphite increases its strength.

Combined Carbon. — In slowly-cooled white iron all the carbon occurs in the form of an alloy, called cementite, which forms in cooling, and the iron partakes of the characteristics of cementite, being hard and brittle, the latter characteristic increasing with an increase in the percentage of the cementite. The carbon in this condition is called combined carbon.

Silicon. — This acts as a precipitant of carbon, drawing it out of combination into graphitic form. The maximum precipitation occurs with from 2.5 per cent to 3.5 per cent of silicon. Beyond this percentage the opposite effect is noted. Increase of silicon up to 3.5 per cent therefore softens the iron, decreases shrinkage, imparts fluidity and reduces the strength. The maximum density of gray iron occurs with about 1 per cent of silicon; more than 2 per cent causes porous iron.

Sulphur. — Sulphur increases the amount of combined carbon, its effect in this direction being far greater than that of silicon in reducing the combined carbon, it being generally considered that 0.01 per cent S will neutralize 0.15 per cent Si. The amount of sulphur should be restricted to a very low percentage. In the Standard Specifications of the A.S.T.M. the sulphur content is limited to not over 0.08 per cent for light castings, not over 0.10 per cent for medium castings and not over 0.12 per cent for heavy castings.

Manganese. — This increases the total carbon and the proportion of carbon in combined form, although by combining with sulphur and reducing the effect of the latter, the net result may be a decrease in the combined carbon. It strengthens the iron if below 1 per cent, strengthens but increases brittleness if between 1 per cent and 1.5 per cent, and if over 1.5 per cent decreases strength and toughness and increases hardness and shrinkage.

Phosphorus. — This causes expansion after solidification, therefore making the iron useful for very thin castings. It, however, tends to make the iron weak and brittle and should be kept below the following values:

	Per cent
Chilled castings	0.3
Malleable castings	0.2
Gray castings	0.7

Use of Cast Iron. — Cast iron should in general not be used where tensile or bending strength is required. Its cheapness and high crushing strength make it useful for heavy parts of machinery, and for pieces where intricate patterns not easily made by tools are needed. It is frequently used for water pipes, despite its low tensile strength, and often for columns in buildings, although cast-iron columns have been superseded to a considerable extent by steel columns, except for the simplest forms of construction. Car wheels of cast iron with the outer surface chilled by iron molds are much used.

Compressive Strength. — The ultimate compressive strength of cast iron is from 60,000 to 200,000 lb. per sq. in. A safe working value for cases where

column action cannot occur is 16,000 lb. per sq. in. For columns the following formula may be used if the applied load is not eccentric.*

$$\frac{P}{A} = 6100 - 32\frac{l}{d},$$

in which

P = total allowable load in pounds,
A = cross-section area in square inches,
l = length unrestrained against lateral deflection in inches,
d = diameter, or shortest side of rectangular column, in inches.

Tensile Strength. — Ultimate strength may vary from 15,000 to 35,000 lb. per sq. in., but is ordinarily from 18,000 to 22,000 lb. per sq. in. For cast-iron water pipes, it is usual to specify 3,300 lb. per sq. in. or 1/5 of the tensile strength, assuming the latter to be 16,500 lb. per sq. in.

Modulus of Elasticity varies from 10,000,000 to 30,000,000 lb. per sq. in. For ordinary foundry iron the modulus of elasticity may be taken as from 12,000,000 to 15,000,000 lb. per sq. in.

Elastic Limit.— Cast iron has no well-defined elastic limit.

Specifications for Cast Iron. — See *Year Book of the American Society for Testing Materials.*

Cost of Cast Iron. — See *Castings, Iron and Steel.*

MALLEABLE CAST IRON. — This is the name given to cast iron which has had a portion of the combined carbon changed to graphitic carbon in the form of a fine powder by reheating white iron to a temperature somewhat below the melting point. The process used in the United States generally eliminates the carbon entirely from the outer layer. Malleable cast iron is used for parts of agricultural machinery, pipe fittings which have to be threaded, plow shares, etc. It has a much higher tensile strength (from 40,000 to 50,000 lb. per sq. in.) than ordinary cast iron and is more ductile. It is frequently sold as some special form of steel, and should be carefully guarded against by purchasers of small articles such as bevel gears, hammers and automobile drop forgings.

Specifications for Malleable Cast Iron. — See Standard Specifications for Malleable Castings in Year Book of the American Society for Testing Materials.

Cost of Malleable Iron Castings. — See *Castings, Iron and Steel.*

BIBLIOGRAPHY. — See *Bibliography* in article on *Steel.*

[C. M. SPOFFORD.]

* See article on *Structures, Simple* for effect of eccentricity on building columns. It should be noted that the allowable loads on cast-iron columns as given in the building laws of various cities, and summarized in the article on *Buildings, Allowable Unit Stresses in*, are in many instances too high for conservative practice.

IRON, WROUGHT. — (*See also Iron, Pig and Cast; Magnetic Properties of Iron; Steel.*) If commercial iron is mechanically mixed with a suitable amount of slag (*see article on Steel*) there results a malleable material called wrought iron which does not harden when suddenly cooled. It melts at a full white heat, but becomes pasty at a lower temperature, in which condition it can be readily welded. It is ductile when cold.

PROCESS OF MANUFACTURE. — Practically all wrought iron is produced from pig iron by indirect processes although direct processes for production from the ore exist. These indirect processes may be divided into two general classes based upon the type of furnace used: (*a*) reverberatory or puddling furnaces; and (*b*) charcoal hearths. The best iron is made upon hearths, but puddling furnaces produce the larger quantity. The essential difference between the two processes is that in hearths the chief source of oxidation is atmospheric air, and the fuel is burned in contact with the iron, while in puddling furnaces the chief source of oxygen is magnetic oxide of iron, and the fuel is burned in a chamber separate from that containing the iron. A description of these processes follows.

Puddling. — This method consists of melting pig iron in a reverberatory furnace heated either by coal or natural gas. The furnace hearth is lined with oxide of iron. The pig is exposed for about two hours to the continuous action of a flame hot enough to melt it and to remove most of the impurities, but not hot enough to keep pure iron in a molten state. By the action of the flame the molten iron becomes less fusible and finally pasty. After reaching this condition it is puddled by being worked into balls by hand labor. It is then taken from the furnace and squeezed or hammered into blooms, and then rolled into small bars about ¾ inch thick and from 2 to 6 inches wide, called "muck bars." After cooling, these muck bars are cut into short pieces about 2 feet in length, piled into bundles, fastened by iron wire, reheated to welding heat and re-rolled into merchant bars. If the iron is subjected to a second piling, heating and re-rolling, it is called "double refined iron."

Charcoal Hearths. — The following are the more important hearth processes.

1. **Finery Process.** — Charcoal fineries produce "knobbled" iron of a high degree of softness which is much used for boiler tubes.

In the finery process the pig iron is first melted down in a coke or charcoal refinery to remove the silicon, phosphorus, and sulphur, and is then transferred in a molten condition to a charcoal hearth which is still hot from its previous charge. Damp charcoal is thrown in, a low-pressure, unheated blast turned on and the metal agitated to keep it in contact with the blast. After an hour or more the metal is collected into a ball and hammered to remove some of the slag, cut up and reheated in piles. Gray iron may be used in this process.

2. **Walloon Process.** — The Walloon process is used in Sweden for producing wrought iron from Dannemora pig iron, the resulting product being shipped to England, particularly to Sheffield, for conversion into blister steel for use in fine toolmaking.

In the Walloon process long pigs are melted gradually by being pushed forward into a charcoal fire. The molten iron drops through the blast, becoming decarburized, and collects in a pasty mass at the bottom of the furnace. The partially refined iron is then raised to the top of the charcoal fire, and melted down with the addition of rich slag and hammer scale. The metal is then balled, reheated and hammered.

3. Lancashire Process. — The Lancashire process is used principally in Sweden, but is also used in the United States.

The Lancashire process somewhat resembles the Walloon process. Pig iron is melted between two layers of charcoal, the liquid dropping down through the blast and becoming oxidized. The molten metal collects in a pasty mass at the furnace bottom where it is allowed to remain for twenty or twenty-five minutes; it is then mixed with decarburizing slag and remelted in a similar manner. Finally the pasty mass is removed from the hearth and hammered.

Busheled Iron. — "Busheled iron" is made of scrap instead of pig iron. The scrap is heated in a furnace, squeezed and rolled into bars. The resulting product is of inferior quality.

COMPOSITION. — Wrought iron consists of a mass of ferrite interspersed with elongated particles of slag. Commercial shapes of wrought iron, such as plates and rods, are made from piles of muck bars, and have a fibrous character since they consist of a series of welds.

USE. — Wrought iron has been gradually replaced by steel for most structural purposes. Good quality of iron, however, is still in demand where toughness and ductility are necessary, and where welding or other blacksmith work is to be done. Iron of a high degree of purity is sometimes specified for use where a non-corrosive material is needed.

GRADES. — Wrought iron is on sale in the eastern states under the following classification:.

Norway (or Swedish Iron). — Best grade; used for fine wrought work and machine work. It is particularly fibrous.

Double Refined or Best Refined. — This is the best domestic iron. It is used for forging, welding or machine work.

Common Iron.— This is the cheapest grade. Used for nails, horseshoes, etc. It does not weld as readily as other grades.

STRENGTH AND ELASTICITY; WEIGHT. — The values stated in the specifications which follow indicate the tensile strength of wrought iron of the grades specified. The following values are from tests made upon merchant iron at the Massachusetts Institute of Technology, and show the variations that may occur between the various grades bought in the market without specifications. The specifications which follow show the strength which may be obtained in material of the grades specified therein.

TENSILE STRENGTH, MODULUS OF ELASTICITY, ELONGATION, ETC., OF WROUGHT IRON

(M.I.T. Tests)

Item	Single Refined	Double Refined	Swedish
Ultimate strength, lb. per sq. in.....	47,000	51,700	40,600
Elastic limit........................	32,000	25,800	20,900
Yield Point..........................	35,000		
Modulus of Elasticity...............	27,700,000	29,700,000	29,100,000
Per cent of elongation in 10 inches..	....	22.7	26.4
Reduction per cent..................	20.6	37.5	75.0

Compressive Strength. — For all practical purposes this may be taken as the yield point, or from 3000 lb. to 4000 lb. above the elastic limit.

Weight. — Wrought iron weighs 480 lb. per cu. ft. A bar 1 yard in length and 1 sq. in. in cross-section weighs 10 lb.

STANDARD SPECIFICATIONS FOR WROUGHT IRON. — See *Year Book of the American Society for Testing Materials.*

COST. — The following quotations are taken from *The Iron Age*, Jan. 2, 1913.

Iron bars, Philadelphia......................1.675 cents per lb.
Pittsburgh........................1.70 cents per lb.
Chicago..........................1.575 cents per lb.

On the same date small quantities were for sale in Eastern cities at the following prices:

Norway iron, 3.00 cents to 3.60 cents per lb.
Double Refined or Best Refined, 2.50 cents per lb.
Common Refined, 2.00 cents to 2.10 cents per lb.
Borden's Best Bar Iron, 3.35 cents per lb.

Prices vary considerably, weekly quotations being given in *The Iron Age.*

BIBLIOGRAPHY. — See bibliography in article on *Steel.*

[C. M. Spofford.]

LAMPS, ARC. — (*See also Arc, Electric; Distribution and Transmission Systems; Lamps, Incandescent; Illumination, Street; Photometric Quantities; Photometry; Rectifiers.*) The theory of the electric arc is discussed in detail in the article on *Arc, Electric*. Arc rectifiers are discussed in the article on *Rectifiers*. This article deals with the use of the electric arc as a source of illumination.

The positive and negative electrodes are termed respectively anode and cathode. The active conducting medium of the arc is supplied by the electro-vaporization of the cathode. The wasting of the anode is due only to its oxidation and can be prevented without interrupting the arc by cooling or by isolation from air. With the exception of the carbon arc, it is more difficult to maintain an arc with alternating than with direct current.

Voltage Drop Across an Arc. — The voltage drop across an arc comprises three elements, (1) a sensibly constant drop at the anode, (2) a similar but much smaller drop at the cathode and (3) a variable drop in the arc stream. The electrode drops depend only on the nature of the electrodes. The drop in the arc stream varies with the current according to Ohm's law, but the relation is greatly complicated by the changes in the resistance of the arc stream. Steinmetz (*Radiation, Light and Illumination, p. 139*) proposes the following general expression for arc conduction in air:

$$E = E_0 + \frac{k\,(l + l_1)}{\sqrt{I}},$$

where E is the total voltage, E_0 the electrode drop, l the arc length in inches, I the current, and k and l_1 constants depending on the cathode material.

For carbon electrodes, $E_0 = 36$, $k = 130$, $l_1 = 0.33$.
For magnetite-copper electrodes, $E_0 = 30$, $k = 123$, $l_1 = 0.05$.

Steadying Resistance. — When the arc is employed in a series circuit its instability is overcome by supplying it with a constant current. Arcs in multiple on constant-potential circuits must each be compensated by a considerable ballast of stable series resistance or reactance; see article on *Arc, Electric*.

Power Factor. — Due to the distortion of the current wave by the varying resistance of the arc, the alternating-current carbon arc has a power factor of about 85 per cent, although the current and voltage pass through their zero values simultaneously; see *Alternating Currents*. Reactive ballast coils used in constant-potential lamps reduce the over-all power factor to values between 60 and 75 per cent.

Sources of Luminosity. — There are three distinct modes of light production by electric arcs, viz., (1) by incandescence of the electrodes due to their high temperature, (2) by the luminescence in the arc of salts derived from mineralized carbon electrodes, and (3) by the luminescence in the arc of the conducting vapors from the cathode. The first is exemplified by the ordinary carbon arc. The second mode is exemplified by the flame arc. The color of the light and its efficiency depend on the nature of the luminescent salts and the temperature attained in the arc. Carbon electrodes heavily mineralized with calcium salts yield a yellow light of high efficiency. Barium salts yield white light and strontium red, but the efficiencies are lower than those attained with yellow light. The third mode is exemplified in the metallic arcs, the chief practical representatives being the magnetite and the mercury arcs. Here the color of the light depends solely on the natural spectrum of the cathode vapor and the efficiency depends on the richness of that spectrum in highly luminous components.

Steadiness of Light. — Light from arc lamps is inferior to that from incandescent lamps in the matter of steadiness. The conditions requisite for

steady light are constant arc length, constant current, fixity of arc position, uniform feed, homogeneous electrodes and complete protection from drafts. When well ballasted the mercury arc in the vacuum tube best meets these conditions. The alternating-current arc displays instantaneous variations in intensity which are very annoying at low frequencies. Arcs should not be operated at less than 40 cycles per second where considerations of hygiene are important. The three-phase arc is free from this defect.

CARBON ARC LAMPS.— Unless used for indirect light the upper electrode of a direct-current carbon arc should be the anode in order to gain the fullest advantage of downward light distribution from the crater. In the alternating-current arc semi-craters of lower temperature are formed on both electrodes, resulting in lower efficiency of light production than in the direct-current arc. The performance of typical carbon arc lamps is given in Table I and Fig. 1.

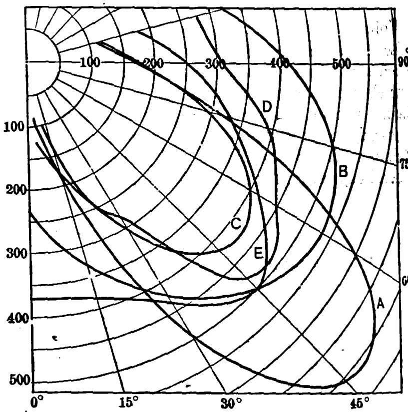

Fig. 1. Light Distribution of Typical Carbon Arcs.

A. 6.6-amp. series D-C. open arc, clear globe.

B. 6.6-amp. series D-C. enclosed arc, opal inner, and clear outer globe.

C. 7.5-amp. series A-C. enclosed arc, opal inner, and clear outer globe, small reflector.

D. 5.5-amp. multiple D-C. enclosed arc, 110 volts, opal inner, clear outer globe.

E. 5-amp. multiple D-C. intensified arc, 110 volts, opal inner, and clear outer globe.

Open Carbon Arcs. — The open arc is characterized by the rapid oxidation of the electrodes due to the free access of air. The anode of a direct-current open arc wastes at a rate between 1 and 2 inches per hour and the cathode at about half the rate of the anode. The electrodes of open alternating-current arcs burn from 1 to 1.5 inches per hour. A life per trim sufficient for all-night operation may be obtained by the use of a single pair of very long, heavy carbons or by providing two sets for successive consumption. The open arc is very sensitive to drafts. It is operated with short arc length, low voltage, usually 45 to 55, and heavy current, usually 6.6 to 10 amperes, to improve the steadiness of the light. The short arc length impedes downward light distribution and the intense crater casts harsh shadows. The erratic travel of the arc about the electrodes makes the light very unsteady. The use of the open arc is now confined to series circuits.

Inclosed Carbon Arcs. — The inclosed carbon arc with closely restricted air supply affords a greatly increased electrode life over the open type. It is also much less liable to extinction by wind, and hence can effectively employ greater arc length, higher voltage and lower current than the open arc. The crater of the inclosed arc is less pronounced, entailing some loss of efficiency compared with the open arc, but the greater length of the arc reduces the interference of the lower carbon with downward distribution. The light is much steadier than

that from the open arc. It is bluer in color, due to the greater proportion derived from the arc proper. Electrodes of moderate length afford a life per trim of from 80 to 100 hours in alternating-current lamps and of 100 to 150 hours in direct-current lamps. The range of currents in common practice is from 3 to 7.5 amperes.

Intensified Carbon Arc. — The intensified carbon arc, used only on direct-current circuits, employs a short, thick vertical lower carbon as cathode and two long, thin, inclined carbons as anode. The upper carbons converge just above the cathode and feed downward at the rate of consumption without the aid of any regulating mechanism. The lower carbon is controlled by a feeding solenoid and tends to maintain an arc of constant length at a fixed level. The high current density in the positives produces a very intense dual crater which emits light of somewhat whiter quality and of higher efficiency than that of the ordinary inclosed arc. The fixed level of the arc and the absence of crater travel aid in the effective use of reflectors and diffusing globes and in the maintenance of a definite form of light distribution. Under standard conditions of use the 5-ampere arc has a life per trim of from 80 to 100 hours.

D. 10-amp., 55-volt, A-C. white flame arc, clear inner and outer globes, vertical electrodes, enclosed type.

FLAME ARC LAMPS. — The flame arc depends for light production on the luminescence of salts impregnated in carbon electrodes. In its electrical characteristics it is essentially a carbon arc. The evolution of this type of lamp has been along two structural lines, one having vertical electrodes, introduced by Blondel, and the other having converging electrodes, introduced by Bremer. In both types both electrodes are fed by the regulating mechanism and the arc is maintained at a fixed level beneath a vitreous canopy or economizer which serves to conserve the heat of the arc, deflect the fumes to the ports at the periphery of the housing, and to assist in the downward reflection of light. Flame arcs may be either open or inclosed. The performance of typical flame arcs is given in Table II and Fig. 2.

Open-flame Arcs. — The open type provides positive ventilation to sweep the fumes of the arc from the arc inclosure and to prevent their deposit on the inclosing globe. The unrestricted air supply causes a rapid wasting of the electrodes. To obtain a practicable life per trim the electrodes are made either

very long or of very great cross-section. The co-axial arrangement of very long electrodes is obviously impracticable; hence the converging arrangement. The slender electrodes afford additional advantages through the high current density at the arc, absence of arc travel and low heat loss by conduction. A magnetic blow coil is employed to hold the arc in its proper position below the electrode tips. Lamps of this type have a maximum luminous intensity in the downward direction, and hence must be hung very high to produce uniform illumination. The open-flame arc with converging electrodes has a life per trim of from 10 to 15 hours. The open type with vertical electrodes has a life per trim of from 12 to 18 hours, but produces a less steady light than the converging type, due to arc travel.

The ventilating system of open-flame arcs requires very careful design. Unless the fumes are positively removed from the inclosing globe, the accumulation of powder on the globe during the life of a single pair of electrodes may reduce the light transmitted by as much as 40 per cent.

Lamps of the open type are greatly handicapped by the high cost of maintenance and electrodes.

Inclosed Flame Arcs. — The inclosed type of flame arc is provided with a condensing chamber into which the fumes of the arc are carried by convection, as shown in Fig. 3. The gases are thus cooled and freed from their solids without rapid ingress of air. The life of the electrodes is thus prolonged about ten times, giving a life per trim of from 100 to 150 hours. The electrodes used in inclosed flame arcs are less highly mineralized than those used in open arcs and the gain in life is accompanied by some loss in efficiency. The converging carbon type of flame arc has not been developed in the inclosed form.

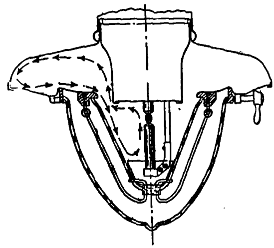

Fig. 3. Method of Condensation of Gas in Inclosed Flame Arc

MAGNETITE ARC LAMPS. — The magnetite arc depends for light production solely on the luminescence of the conducting vapors produced at the cathode. The cathode consists of a thin iron tube closely packed with a uniform powdered mixture of magnetite, oxide of titanium and oxide of chromium. The positive electrode is a block of copper of large heat-radiating capacity. The magnetite produces an arc of excellent conductivity, but of relatively lean spectrum. The titanium oxide enriches the spectrum of the arc, improving its color and efficiency. The oxide of chromium serves to restrain the rate of vaporization of the active elements and so prolong their life. The resulting light is of excellently balanced white color. The copper anode is not consumed and requires infrequent replacement. The cathode has a life of from 100 to 250 hours depending on the current and arc length. It is not practicable to operate the magnetite arc in an inclosure with limited air access, due to the need of ventilation to remove the copious brown fumes. The light of the magnetite arc is relatively unsteady, a feature which is aggravated by the intermittent method of feeding employed.

The two commercial types of magnetite arc differ principally in the electrode arrangement. In the General Electric type the positive is the upper; in the Westinghouse type the negative is the upper. The advantages claimed for each type conflict sharply.

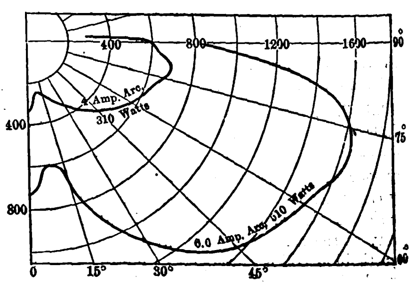

Fig. 4. Light Distribution of Magnetic Arc in Clear Globes

Unlike other types of arc lamps the magnetite arc is poorly adapted to interior use on constant potential circuits. Its field is therefore largely confined to street lighting on constant-current circuits. While the magnetite arc is solely a direct-current device, it is readily adapted to use in connection with an

alternating-current supply by the use of the mercury arc rectifier combined with the constant-current transformer; see *Rectifiers*.

The voltage range per lamp on series circuits is from 75 to 80. The standard currents are 4, 5 and 6.6 amperes. The performance of typical magnetite arcs is given in Table III and Fig. 4.

LOSS OF CANDLE POWER OF CARBON AND FLAME ARCS.—The light output of all types of arc lamps falls off gradually during the life of each set of electrodes, due to the accumulation of ash and fumes on the glassware. The amount of this loss varies greatly with the conditions. Matthews (*Nat. Elec. Light Assn., 1901, p. 296*) reported tests of inclosed carbon arcs of which the following results are typical, viz., reduction of light output in 100 hours, best grades of carbons 5 per cent, low-grade carbons 30 per cent. In carbon arcs this loss depends chiefly on the purity of the carbons employed. The loss in flame arcs depends on the scheme of ventilation and the extent to which the carbons are mineralized. Composite results of many tests on inclosed flame arcs reported in *Good Lighting*, Vol. 7, p. 515, show a loss in 100 hours burning of 23.5 per cent of the initial mean lower hemispherical candle-power. Tests on General Electric inclosed white flame arcs made at the Massachusetts Institute of Technology (*Wright and Sprowls, 1912*) showed the average reduction of light in 150 hours burning to be 18 per cent. The loss of light in magnetite arcs is relatively small, due to the positive character of the ventilation. The importance of very careful cleaning of glassware of arc lamps at each trimming is apparent from the above data.

EFFECTS OF DIFFUSING GLOBES.—The intrinsic brilliancy of all arcs is sufficiently high to seriously interfere with good vision when in the direct field of view. Diffusing globes reduce the light by from 25 to 40 per cent through absorption, but generally serve to increase the effectiveness of vision to a degree which fully compensates for the loss of light. Diffusing globes tend to modify light distribution toward greater uniformity at various vertical angles; hence pronounced side-wise distribution must be attained by a properly designed reflector.

REGULATING MECHANISMS FOR CARBON AND FLAME ARCS.—The regulating mechanism of an arc lamp serves the following functions: (1) to strike the arc upon lighting, (2) to feed one or both electrodes at the rate of consumption and (3) to maintain approximately constant the arc length, voltage and current. Feeding systems are of two general classes. In the first the electrodes are fed by gravity upon the releasing of a clutch controlled by solenoids. As the feeding steps are small and frequent the process approaches a uniform continuous feed. In the second type the arc is restruck at each feeding, as in the magnetite arc.

Gravity-feed Mechanism for Multiple Carbon Arcs.—The mechanisms of constant-potential lamps are practically all of the gravity-feed type. The commonest type has a ballast of resistance or reactance in series with a solenoid and with the arc itself; see Fig. 5. When the arc is not lighted the carbons are in contact. When the switch is closed the solenoid is energized and draws its plunger, tightens the clutch and strikes the arc by drawing the carbons apart. As the arc lengthens the current falls until the forces on the plunger are balanced. As the arc lengthens by burning away, the current tends to fall, releasing the clutch and permitting the carbon to feed until checked by the rising of the plunger. In a well-adjusted lamp this process is practically continuous. In alternating-current mechanisms of this type the plungers are laminated and the ballast consists of a reactive coil.

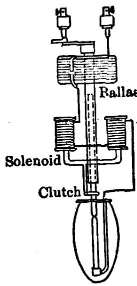

Fig. 5. Multiple Carbon Arc Lamp

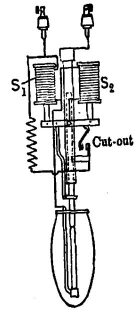

Fig. 6. Series Carbon Arc Lamp

Gravity-feed Mechanism for Series Carbon Arcs.—The commonest type of mechanism for gravity-feed lamps of the series class employs the differential action of two solenoids to control the feeding clutch. Fig. 6 shows this type of mechanism as applied to the inclosed carbon arc. It provides a solenoid S_1 in series with the arc, a solenoid S_2 and resistance coil in parallel with the arc, and a short-circuiting cut-out. The solenoids act differentially on the clutch. The shunt solenoid when strengthened tends to release the clutch, the series solenoid to lift it.

When the lamp is idle the carbons are normally in contact. When current is switched on, the series solenoid is energized and draws out the arc. The cut-out opens, S_2 is energized and tends to oppose the drawing action of S_1, equilibrium being attained when the arc has the proper length. As the carbons burn apart S_2 is strengthened and releases the clutch momentarily, allowing the upper carbon to feed by gravity. If the circuit through the arc is accidentally broken, S_2 alone is energized and the cut-out is immediately closed, preventing the interruption of the circuit. Alternating-current mechanisms have laminated plungers, but differ in no essentials from those in direct-current lamps.

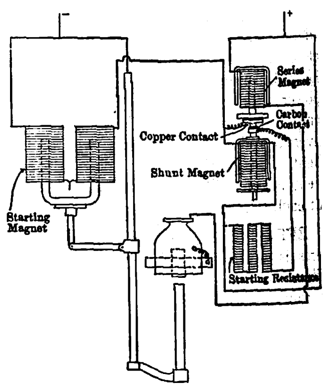

Fig. 7. Mechanism and Circuits of G. E. 4-amp. Arc Lamp

Intermittent Feed Mechanism.—The intermittent type of feeding mechanism for series lamps is shown in Fig. 7. When the current is switched on, the starting magnets are energized, bring the electrodes together and cause the arc to strike. As the electrode burns away the arc gradually increases in length

and potential drop until the shunt coil is sufficiently energized to momentarily short-circuit the arc and cause the striking process to be repeated. As the electrodes come together with considerable force the accumulated slag is broken from the end of the cathode.

Feed Mechanisms for Flame Arcs. — The mechanisms of flame arcs with vertical carbons differ only in details from those of carbon arcs of analogous type, with the exception that the feeding device is dual and acts on both carbons, tending to maintain the arc at a fixed level. Mechanisms for converging carbon flame arcs exist in great variety. The most generally-used type for constant potential operation has a series coil whose plunger acts laterally on one electrode to draw out the arc and gravity feed. In many cases an escapement clutch controlled by a shunt solenoid is used to regulate the rate of feed. In another type the rate of feed is controlled by a metal fin attached to each electrode. The base of this fin rests against a refractory lug. The fin is vaporized away by the heat of the arc at a rate exactly corresponding to the required rate of electrode feed.

MERCURY-VAPOR LAMPS. — (*See also Rectifiers.*) The luminous element of this type of lamp is a luminescent arc, in a highly evacuated tube of glass or quartz, formed between a mercury cathode and an anode of mercury or other metal not attacked by it. The voltage required to sustain such an arc, when the cathode (negative electrode) is mercury, consists of a constant drop at the electrode of about 13 volts and an arc stream voltage which is directly proportional to the length. The arc voltage per inch increases with the vapor pressure. At low vapor pressures the arc is an unstable conductor and the arc voltage per inch falls with a rising current. At high pressures, as in the quartz-tube lamp, the arc voltage rises very rapidly with the current.

The large output of actinic radiation from mercury-arc lamps gives them special advantages in the fields of photography and blue-printing. The large ultra-violet radiation from quartz-tube lamps not inclosed in glass may be utilized in a wide variety of processes for bleaching, sterilization, etc.

Power Factor of Mercury-arc Lamps. — The mercury arc can be sustained at ordinary voltages only when the mercury electrode is the cathode; this principle is utilized in the mercury-arc rectifier (*see Rectifiers*).

To operate a mercury-arc lamp with alternating current the tube is provided with two anodes which are attached to the respective terminals of a reactance coil bridging the line. The cathode is attached to the middle point of this reactance bridge. The power factor of this type of arrangement, including the wave distortion and the lag produced by the reactance coil, is from 50 to 60 per cent.

Glass-tube Mercury-arc Lamps. — The glass-tube type of lamp operates at a low vapor pressure and temperature. Its spectrum is that characteristic of the mercury arc which is entirely deficient in red lines and has a great preponderence of yellow, green and violet.

The very low intrinsic brilliancy of this type of lamp renders diffusing glassware unnecessary. Its simple color composition tends to enhance the acuity of vision. For general use the spectrum is perceptibly improved by combining with the arc a parabolic reflector coated with rhodamine enamel, which by fluorescence converts part of the blue and violet radiation incident upon it to red and orange rays.

Methods of Starting. — The mercury arc is started either by tilting the tube until mercury from the cathodes makes metallic contact with the anode and strikes the arc or by breaking down the gap by a high-potential spark discharge. As installed for general lighting the mechanism usually in-

cludes an automatic starter operating on one of the two methods referred to. The tilting mechanism is operated by a solenoid which is cut out as the arc is struck. The spark-discharge device is essentially an automatic quick-break switch which opens the circuit of an induction coil so as to cause it to discharge through the tube. The mechanism also includes a ballast coil to compensate for the instability of the arc. The tube is mounted in an inclined or vertical position. The mercury vapor condenses at the top in a condensing chamber and is restored to the cathode by gravity.

Performance of Glass-tube Mercury-arc Lamps. — Performance data on several typical lamps of this class are given in Table IV.

TABLE IV. — DATA ON GLASS-TUBE MERCURY-VAPOR LAMPS

Type	K (*D-C.*)	H (*D-C.*)	P (*D-C.*)	F (*A-C.*)
Volts	100 to 124	50 to 62*	100 to 124	95 to 250†
Amperes	3.5	3.5	3.5	....

Watts per M.L.H.C.P.	0.55	0.64	0.48	0.52

* To be operated as one or more pairs in series.
† Adjustable to circuit voltage by auto-compensator.

Life of Glass Tubes. — Tubes fail ultimately through breakage or through deterioration of vacuum. The life per tube varies considerably, but is usually several thousand hours of operation.

Loss of Candle Power with Age. — The light output of glass-tube lamps deteriorates quite rapidly during the early portion of tube life. Tests reported by Harrison (*Trans. Ill. Eng. Soc., Vol. 6, p. 545*) give the following average value on two type *H* tubes operated at 3.3 amperes:

Per cent initial candle power....	100	83	80	77	73	70.5	67
Hours burning................	0	250	500	1000	2000	3000	4000

Quartz-tube Mercury-arc Lamps. — The quartz-tube lamp operates at a high temperature and pressure. Its luminescent spectrum is richer than that of the low-pressure lamp and has superposed upon it a continuous spectrum of incandescence including all luminous elements. The light of the high-pressure lamp is therefore much nearer white than that of the low-pressure lamp. On account of the high pressure of the arc in the quartz tube the length required for circuits of commercial voltage is very much less than the length of glass-tube arcs. The quartz-tube lamp emits a considerable amount of invisible ultra-violet radiation which is capable of doing serious injury to the eye. Ample protection is afforded by surrounding the tube by an envelope of clear glass. Quartz tubes are nominally indestructible, but may require occasional repumping.

The performance of several typical quartz-tube mercury-arc lamps is given in Table V.

COST OF ARC LAMPS. — Open carbon-arc lamps are no longer sold. Inclosed carbon-arc lamps cost from $16 to $20 a piece. Magnetite and metallic oxide arc lamps cost from $23 to $27. The first cost of flame-arc lamps is from $33 to $45. Glass-tube mercury-arc lamps cost complete, including reactance coil, from $33 to $35, and quartz-tube mercury-arc lamps cost complete from $65 to $75; the latter, however, are not yet used to any great extent. The renewal cost of short glass tubes is approximately $5.50, that of long glass tubes $10.50 to $12.

TABLE V.—PERFORMANCE OF QUARTZ-TUBE MERCURY-VAPOR LAMPS

Type	X	Y	Z

Watts per M.L.H.C.P.	0.42	0.30	0.31

Annual Costs.—The following comparative costs of arc-lamp operation under street lighting conditions for a total of 4000 hours (one year, all night service) are given by Friedman (*Elec. World, Vol. 55, p. 1071*).

ANNUAL COST OF OPERATING ARC LAMPS

Type / Amperes	Open d-c. 9.6	Open d-c. 6.6	Enc. a-c. 7.5	Enc. d-c. 6.6	Enc. a-c. 6.6	Magnetite 4.0	Magnetite 6.6
Electrodes	$5.50	$5.50	$1.50	$1.20	$1.20	$1.55	$2.85
Trimming	6.00	6.00	2.00	2.00	2.00	1.00	2.00
Repairs	2.50	2.50	1.00	1.00	1.00	0.75	0.75
Inner globes	......	......	0.45	0.45	0.45	......	......
Outer globes	0.30	0.30	0.30	0.30	0.30	0.50	0.50
Renewals of station equipment	1.50	1.50	......	1.50	......	2.00	3.00
Energy, 1.5 cts. per kw-hr	50.00	32.70	34.50	42.90	30.30	22.80	38.82
Totals	$65.80	$48.50	$39.75	$49.35	$35.25	$28.60	$47.92

The above costs do not include fixed charges. Interest may properly be taken at 6 per cent and depreciation at from 7.5 to 10 per cent.

Comparative operating costs of flame arcs are given by Blake (*Gen. Elec. Rev., Dec., 1911*) for 1000 hours of operation as follows:

Type	Open flame	Inclosed flame
Life per trim	17 hours	100 hours
Cost of electrodes per trim	$0.15	$0.20
Cost of labor per trim	0.04	0.04
Maintenance per 1000 hours:		
Electrodes	8.81	2.00
Trimming	2.35	0.40
Globes	0.09	0.22
Totals	$11.25	$2.62

In addition to these costs allowance may be made for repairs at $1 per annum and for energy at a suitable cost per kw-hr. Interest and depreciation must be allowed as before stated.

[W. E. Wickenden.]

LAMPS, INCANDESCENT ELECTRIC. — (*See also Illumination, Laws of; Illumination, Interior; Illumination, Street.*) Incandescence denotes the emission of light by a solid or liquid body due to its temperature elevation. The performance of incandescent bodies is referred to a standard *black body,* or one which, at any temperature, emits the maximum possible intensity of radiation at each wave-length of the spectrum. The percentage of luminous radiation from incandescence is low, but increases markedly with the temperature. Hyde computes the luminous radiation from a black body as 1.9 per cent at 2000° C. Abs., 8.8 per cent at 2500° C., 16.9 per cent at 3000° C., 32.5 per cent at 4000° C., 44 per cent at 5000° C. and a maximum of 50 per cent at 6500° C. Certain materials excel the black body in relative light radiation due to *selectivity* or the relative depression of heat radiation as compared with light.

The efficiency of the incandescent lamp depends on: (a) the temperature which its filament can sustain without an undue rate of decay; (b) the degree of selectivity manifested; and (c) the prevention of thermal leakage by conduction and convection. These conditions require a filament of the highest obtainable melting point and lowest vapor tension, which must be isolated in a vacuum and supported by a system of low thermal conductivity. So fully are the two latter conditions met that the thermal leakage of modern lamps is less than 5 per cent.

Electrical and Mechanical Properties of Lamps. — The specific resistance of the filament material should be relatively high to insure favorable dimensions in units of low power and high voltage. A relatively large positive temperature coefficient of resistance is desirable as this tends to lessen the variations in performance caused by voltage fluctuations. The filament should be of great mechanical strength, especially in its resistance to fracture. The material required should be obtainable in ample quantities, readily workable and uniform in its finished state. Experience indicates that alloys are distinctly inferior to pure metals and metalloids in all essential features.

Vacuum. — Incandescent lamps require the highest practicable vacuum for the chemical and thermal protection of the filament. In the manufacture of lamps the first stage of evacuation is mechanically produced. Final exhaustion is produced chemically by burning within the inclosure a small amount of phosphorous compound. During the latter stage the filament is raised to incandescence to drive off residual gases. To prevent the loss of vacuum through the unequal expansion of the glass and the leading-in wires the latter are made of platinum.

TYPES OF LAMPS. — There are described in the following paragraphs the types of incandescent lamps which have become of commercial importance. Of the several types the gem (metallized carbon filament) and the tungsten filament are at present the most widely used.

Carbon Lamps. — Carbon vaporizes at about 3900° C. and exists in a variety of forms which vary greatly in other physical properties. *Base carbon,* prepared as lamp filaments by carbonizing squirted threads of dissolved cellulose, is of low conductivity, high vapor tension and of negative temperature coefficient of resistance. *Graphitic carbon,* which is deposited from hydrocarbon vapors on incandescent filaments of base carbon, has a high conductivity, low vapor tension and a small positive temperature coefficient. *Metallized carbon,* prepared from the two preceding types by heat treatment in an electric furnace, has a greatly increased conductivity, a pronounced positive temperature coefficient, low vapor tension and a fair degree of selectivity. The common carbon lamp has a core of base carbon on which a shell of graphitic

carbon has been deposited by the process of flashing. The hot resistance of this type is approximately half the value cold. The chief advantage of this type is its low cost and great ruggedness. It is being rapidly superseded by the metallized-carbon type, commercially known as the gem lamp, which has a higher efficiency and better color. The hot resistance of the gem lamp is 2.6 times its value cold.

Tantalum Lamps. — Tantalum melts at about 2800 deg. C; has a very low vapor tension, its atomic weight being 183; a high conductivity, 6.5 microhms per cm. cube at 25° C., and of 38.8 microhms at its operating temperature; a mean temperature coefficient between 0° and 100°C. of + 0.00234; and a valuable degree of selectivity. Tantalum is readily drawn into filaments of minute diameter. Tantalum filaments undergo a gradual deterioration in structure with use, especially when operated by alternating current. This change reduces the life of the lamp and limits its general usefulness. The tantalum lamp is now largely superseded by the tungsten lamp.'

Tungsten Lamps. — Tungsten melts at about 3200 deg. C.; has a low vapor tension, its atomic weight being 184; has a conductivity of 6.2 microhms per cm. cube at 25° C. for the hard-drawn variety and 5 microhms for the annealed; has a mean temperature coefficient of + 0.0051 between 0° and 170° C. and is selective in radiation to a valuable degree. The hot resistance of the filament is from 10.8 to 13 times the cold resistance, depending on the type of lamp. Tungsten is exceedingly hard and is worked with difficulty. Early filaments were produced by sintering finely divided tungsten reduced from tungstic oxide; they were extremely fragile and were uncertain in performance. Methods of drawing continuous filaments are now in vogue, giving a product of great strength and uniformity. Prior to 1912 much difficulty was experienced with the erratic blackening of bulbs. This fault is now (1914) largely overcome by the introduction into the bulb of a special chemical. The tungsten lamp of American manufacture is commercially known as the Mazda lamp.

Nitrogen-filled Lamps. — This type of lamp has a closely coiled helical filament of drawn tungsten wire mounted in a glass chamber filled with nitrogen or other inert gas. The pressure of the gas retards the decay of the filament so that it may be operated with a satisfactory life at a higher temperature than is practicable in a vacuum. The gain in radiant efficiency so obtained is offset in part by the convection of heat from the filament by the gas. When the diameter of the filament is minute there is little or no net gain in efficiency. When the filament is relatively heavy the net efficiency may be doubled. The helical coiling of the filament increases its effective diameter as a radiant and simplifies the problem of its support, for the filament is distinctly soft when incandescent. The gas-filled lamp has an elongated bulb, the upper portion of which serves as a cooling chamber. The walls of this chamber receive the black deposit from the filament, but are so placed that they absorb but little of the useful light. The gas-filled lamp is designed for operation in a pendant position. Such lamps are much more brilliant than vacuum lamps and should be fully shaded. The light of the gas-filled lamp is decidedly whiter than that of the vacuum tungsten lamp.

Nernst Lamps. — This type of lamp enjoyed considerable vogue prior to the development of the drawn-wire tungsten lamp but is rapidly becoming obsolete in America. Its luminous element consists of a glower of refractory rare earth oxides operating in the atmosphere. The glower is a non-conductor when cold but its resistance decreases greatly with rise of temperature. A separate heater element is employed to bring the glower to incandescence and a series ballast resistance is used to correct the instability of its conduction. After the

period of ignition the heater is disconnected by a solenoid cut-out. It is impossible to operate the glower in a vacuum owing to the electrolytic nature of its conduction. Its performance on direct current is inferior to that on alternating current. The lamp has the advantage of an inherently good light distribution downward, but its disadvantages are marked, viz., complexity, slow ignition, costly renewals, non-adaptation to ordinary sockets, and efficiency inferior to metal-filament **lamps.** Under the best conditions with clear glass globes, a performance of from 1.4 watts per mean lower hemispherical candle for the smallest to 1.10 watts per m.l.h.c.p. for the largest types is realized. The alabaster globes usually employed with Nernst lamps increase the watts per candle performances by about 10 per cent.

Use of Various Types of Lamps. — The following table shows the relative use of each of the four types of lamps produced for domestic sale in recent years as reported by the Lamp Committee of the Nat. El. Lt. Assoc. in 1913.

Type of Lamp	1907	1908	1909	1910	1911	1912
	Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
Carbon	93.27	84.12	68.98	63.08	52.90	25.47
Gem	5.88	8.58	15.07	14.88	19.00	33.50
Tantalum	0.75	1.78	2.12	3.57	2.74	1.00
Tungsten	0.10	5.52	13.83	18.47	25.30	39.94

There is a marked tendency away from the carbon lamp. Many electric light companies have substituted the gem type for the carbon in their free renewal service. The total domestic consumption of incandescent lamps was approximately 85,000,000 in 1911 and 90,000,000 in 1912.

LAMP RATINGS AND PERFORMANCES. — Constant potential lamps are rated primarily by watts and normal voltage, constant current lamps by amperes and candle-power. Secondary ratings of mean horizontal candle-power, mean spherical candle-power, total lumens, watts per mean horizontal candle-power, lumens per watt, and average life at rated efficiency are usually given by makers. Constant potential lamps bear a rating tag giving normal volts and watts. The rating tag of gem lamps has three voltages differing by steps of two volts, and the normal watts for the highest voltage. This type of rating enables the user to vary efficiency and life so as to secure the most economic conditions (*see paragraph below on Cost of Light*). The following table gives approximate data on the relative performance at the three voltages.

PERFORMANCE OF GEM LAMPS AT THE THREE RATED VOLTAGES

Voltage	C. P. Per cent	W. P. C. Per cent	Watts Per cent	Life Per cent
High	100	100	100.0	100
Medium	92	105.2	96.8	140
Low	84	111.5	93.7	190

A similar method of rating other types of incandescent lamps was in use before 1914.

DATA ON CONSTANT POTENTIAL LAMPS

Min.S denotes miniature screw base. CS denotes candelabra screw base.

Performance with Voltage Variations. — The very high rate of change of light produced and of filament life with temperature causes incandescent lamps to be extremely sensitive to variations in voltage. A high positive temperature coefficient of resistance, as in the tungsten filament, affords a partial compensation to voltage variations and increases the stability of the lamp's performance. The relations of candle-power, watts, watts per candle and life to voltage are shown for modern types of lamps in Fig. 2. High voltage increases the candle-power and efficiency, but greatly reduces the life of the lamp. Operating conditions are always a compromise between these three factors. Under ordinary conditions circuit voltage and lamp voltage should agree closely. The effect of low voltage on candle-power is marked. Satisfactory service requires that the voltage be maintained within 3 per cent of the rated value for the lamp. The sensitiveness of life to voltage emphasizes the utter futility of life tests with imperfect voltage regulation.

The relations between lamp performance and voltage may be very completely expressed by a series of simple proportions and exponents:

$$\frac{I_1}{I_2} = \left[\frac{V_1}{V_2}\right]^a; \frac{W_1}{W_2} = \left[\frac{V_1}{V_2}\right]^b; \frac{E_1}{E_2} = \left[\frac{V_2}{V_1}\right]^c; \frac{L_1}{L_2} = \left[\frac{V_2}{V_1}\right]^d,$$

where V = voltage, I = candle-power, W = watts, E = watts per candle, L = life.

The values of the exponents in the above expressions, as determined by the Nat. El. Lamp Assoc., are as follows:

	a	b	c	d
Carbon	5.55	2.05	3.51	20.5
Gem	4.80	1.75	3.06	17.6
Tantalum	4.35	1.74	2.60	14.7
Tungsten	3.68	1.59	2.10	13.8

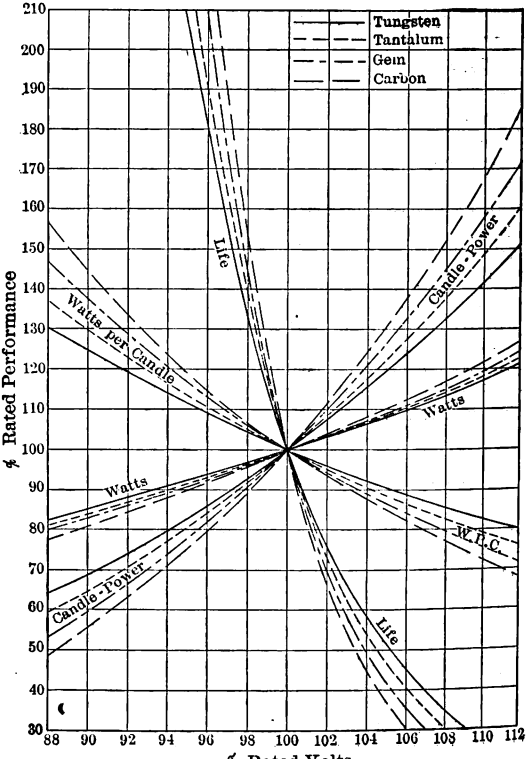

Fig. 2. Characteristic Curves of Incandescent Electric Lamps

Life Performance. — The rated life of incandescent lamps applies to the average of a very large number and not to individual performance. All lamps deteriorate with continued burning in candle-power, efficiency and strength. This decay is partly due to the slow vaporization of the filament and partly to growing light absorption in a black deposit on the inner side of the bulb. The frosting of bulbs, while not accelerating filament decay, hastens the decline of candle-power and efficiency due to the added absorption by the bulb deposit of internally reflected light and the greater tendency of the lamp to accumulate exterior dirt. The effect of bowl frosting is practically negligible. The life curves of Fig. 3 are typical of present-day lamps.

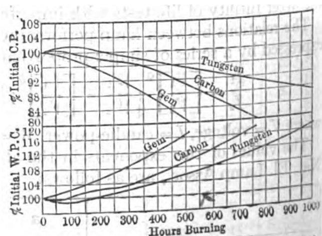

Fig. 3. Life Curves of Typical Incandescent Lamps

Effect of Frequency. — Incandescent lamps operated by alternating current of low frequency produce a flickering light due to cyclic variations of temperature. The flicker is greatest in filaments of small diameter and low thermal capacity, and increases in magnitude as the frequency is reduced. 110-volt carbon lamps of low efficiency have been successfully used with a frequency of 25 cycles. Tungsten street series lamps are satisfactory at 25 cycles. Constant potential tungsten and gem lamps are not as a rule satisfactory at frequencies below 40 cycles.

Smashing Point. — The term "smashing point" denotes the percentage of initial candle-power to which a lamp should be allowed to decline in service to obtain the most economical service. It is apparent from Fig. 3 that continued loss of efficiency ultimately leads to the condition where it is more economical to replace a lamp than to continue it in service. This occurs when the ratio of the total light output, lumen-hours, to date to the total expenditure, lamp cost plus energy cost, has reached its maximum. The smashing point has often been arbitrarily stated as 80 per cent. Recent determinations (*see Bulletin 101 of the Nat. El. Lamp Assoc.*) give the values in the accompanying table, which indicate that in most cases lamps may be economically operated to the point of failure.

Watts	Smashing point, per cent

500	....	....	73.0

COST OF LIGHT BY INCANDESCENT LAMPS. — The main factors in the cost of light are the renewals of lamps and the cost of energy. Minor factors are the labor of inspection, the cost of renewals and the interest on investment in lamps and fixtures. The longer the lamp remains in service the less is the renewal cost chargeable to each lumen-hour and the greater the energy cost. Operating the lamp at better efficiency increases the renewal cost and reduces the energy cost per lumen-hour; at poorer efficiency the reverse is true. The efficiency giving the minimum ultimate cost with any type of lamp is a function of the ratio of the cost of the kilowatt-hour to the lamp cost.

A comparison of Fig. 4 with the table of rated performances shows that the rated efficiencies of commercial lamps agree quite closely with the most economical conditions of use at current lamp and energy prices. The data of Fig. 5 were compiled by A. G. Rakestraw (*Southern Electrician, Oct. 1912*) and include the cost of energy, renewals, interest, repairs and depreciation.

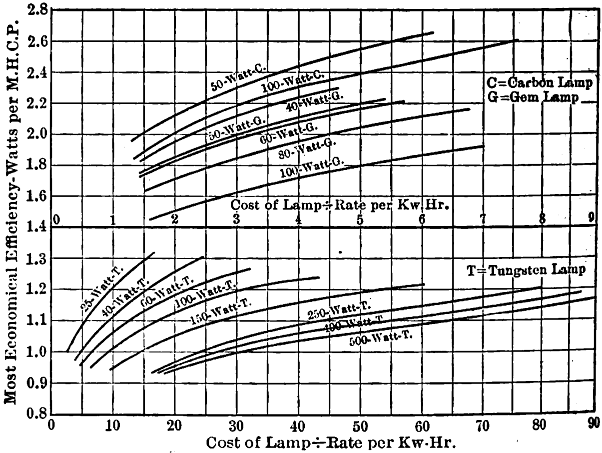

Fig. 4. Most Economical Efficiencies of Carbon, Gem and Tungsten Lamps

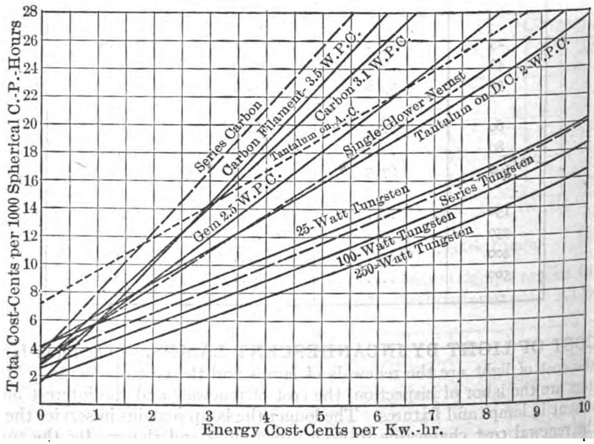

Fig. 5. Cost of Light from Incandescent Electric Lamps

DIFFUSERS FOR INCANDESCENT LAMPS.—Diffusers soften light and reduce its brilliancy by the increase in the area of its apparent source. This is at the expense of considerable absorption (*see table on Absorption of Light by Glassware in article on Illumination, Laws of*). The chief diffusing media are: ground glass, produced by sand-blasting or acid etching; translucent glass of various types, such as alabaster, opaline, opal, milk, etc., which has in

its structure minutely-divided mineral oxides; and prismatic glass. These media are used in frosted bulbs, globes and bowl reflectors partially covering the lamp. The diffusion from ground glass is inferior to that from other media, as the light source is partially visible as a bright spot in high contrast to the surrounding area. Opaline and alabaster transmit a subdued image of the filament but diffuse a considerable portion of the light very effectively. Opal and milk glass are truly diffusing, but are high in absorption. Prismatic globes transmit by refraction innumerable images of small elements of the filament distributed over the entire surface of the globe. When viewed directly the diffusion is imperfect, but to averted vision the effect is excellent. The refracting prisms enable the light distribution to be modified throughout a considerable range. Other diffusing globes tend to equalize light intensity in all directions.

REFLECTORS FOR INCANDESCENT LAMPS. — Reflectors serve primarily to modify light distribution and incidentally to shade the illuminant, to diffuse its light partially and to produce artistic effects. The chief reflecting agencies are polished metal, silvered glass, prismatic glass, opal glass, enamelled metal and aluminum paint. Polished metals, silvered glass and prismatic glass afford a wide latitude in the distribution of light, depending on the contour and depth of the bowl. Diffusely-reflecting surfaces afford less range of control and are not capable of producing strong downward concentration. Prismatic and opal glass reflectors transmit a moderate amount of diffused light and afford some direct illumination for surfaces not receiving the directed beams from the unit. Practically all reflectors are designed for mounting at a definite position with reference to the luminous center of the filament and produce their normal distribution only in this position. The table below gives data on the mean performance of representative groups of reflectors for incandescent lamps.

[W. E. WICKENDEN.]

LIGHTING PLANTS. — (*See also Distribution and Transmission Systems; Illumination, Interior; Illumination, Street; Lamps, Arc; Lamps, Incandescent; Power Stations; Substations.*) Electric lighting systems divide broadly into two classes, viz., series or constant-current, and parallel or constant-potential. The former system is appropriate where a large number of similar lamps in scattered locations are to be controlled simultaneously and where a high voltage can be safely applied to the circuit, as in street lighting. The parallel system is extremely flexible, is adapted only to low voltages and permits the independent control of single lamps and groups.

LOAD CONDITIONS. — The load of a lighting plant varies greatly with the season and with the hours of the day. There is usually a sharply-defined peak load in the early evening which reaches its annual maximum in mid-winter. Storms attended by darkness often give rise to sudden and heavy increases of load. Such conditions demand generating equipment of great flexibility in operation. Sufficient generating capacity must be available to carry the maximum peak load and to provide an ample reserve against accidents. The brief duration of the peak load in many plants makes desirable the selection of types of equipment having large temporary overload capacity in order to decrease the reserve needed. Typical load curves are shown in Figs. 1 and 2.

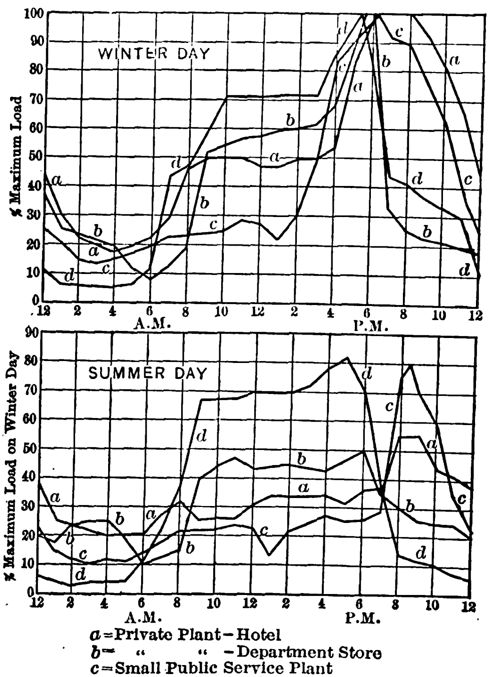

Fig. 1. Load Curves of Lighting Plants

Load Factor and Diversity Factor.— (*See also Standardization Rules of the A.I.E.E.*) The *load factor* of a machine, plant or system is the ratio of the average power to the maximum power during a certain period of time. The *diversity factor* is the ratio of the sum of the maximum power demands of the subdivisions of any system or part of a system to the maximum demand of the whole system or the part of the system under consideration, measured at the point of supply. The investment in a lighting system is largely determined by the peak load to be provided for. The annual charges on this investment are practically independent of the output; hence

the investment expense per kilowatt-hour varies in nearly inverse ratio to the annual load factor. The average annual load factors of lighting installations, of various types, as given by E. W. Lloyd (*Nat. El. Lt. Assoc., 1909, Vol. 2, p. 586*) range from 5 to 29 per cent, with the general average of complete systems less than 20 per cent. The economic advantages of high load factor can be secured in lighting service only by combining it with loads having non-coincident peaks, as commercial power and railway systems. Fig. 2 shows typical load curves and load factors for a typical winter and a typical summer day of (*a*) a city system of lighting and power, (*b*) a city street and elevated railway system and (*c*) the combined load of (*a*) and (*b*). (*Trans. A.I.E.E., 1912, Vol. 31, p. 240.*) The advantage of the diversity factor of these loads is apparent.

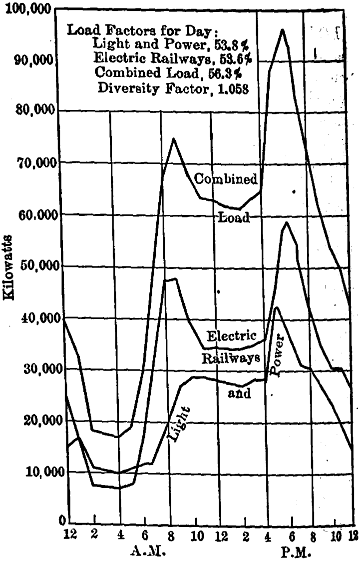

Fig. 2. Load Curves of Composite System on Winter Day. Daily Load Factor: Light and Power 53.8%, Electric Railways, 53.6%, Combined Load 56.3%, Diversity Factor, 1.058

In a general sense an appropriate scale of charges for electric energy should be graded according to the degree to which the load contributes to the system's peak as well as according to the energy consumed. Off-peak loads may appropriately receive low rates. The gain in load factor from diversity often makes it possible for a lighting station to sell energy at wholesale to a railroad system at a cost less than that at which the latter system could generate it independently.

Diversity factors exist between the various subdivisions of a lighting system and have an important influence on the rated capacity and investment required in the several elements of a system. H. B. Gear (*Trans. A.I.E.E., 1910, Vol. 29, p. 375*) reports the diversity factors of various classes of service and branches of the system of the Commonwealth Edison Company of Chicago to be:

DIVERSITY FACTORS OF A LIGHTING SYSTEM

Subdivision of the System	Residence lighting	Commercial power	Scattered power	Large users
Substation to feeders..........	1.15	1.15	1.15	1.15
Feeders to transformers.......	1.8	1.25	2.0	1.25
Transformers to meters........	3.0	1.6	1.1	1.0
Total diversity factor.........	6.20	2.30	2.53	1.44

DIRECT- VS. ALTERNATING-CURRENT SYSTEMS.—(*See also Distribution and Transmission Systems.*) Direct current has the following

advantages for lighting: (1) safety, since the lines are in no way associated with high-voltage conductors; (2) freedom from power factor, reactance and skin effect, which results in superior voltage regulation in heavily loaded low-voltage circuits; (3) the direct availability of the storage battery as a reserve and a load regulator; (4) the self-exciting and self-regulating features of direct-current generators; (5) the superiority of direct-current motors for adjustable speed service and for the operation of elevators and cranes; and (6) the marked superiority of direct-current arc lamps. Direct current is generally used in isolated plants and in congested city districts because of the greater ease with which good voltage regulation is maintained.

The advantages of alternating current are chiefly those incidental to its flexibility of voltage transformation and control, which makes possible an extended range of economical transmission and the independent regulation of separate feeders and lines. Alternating-current generators are less expensive than direct-current machines, being free from commutator limitations and adaptable to much higher speeds.

Voltage. — The range of voltage from 100 to 125 is standard for electric lighting in America. In England and to some extent on the continent the 200- to 250-volt range has been extensively used. The higher range lends itself to more economical distribution of power, the lower range to the superior construction of incandescent and arc lamps. The Edison 3-wire system of distribution is largely used in direct-current systems. The voltage generated for alternating-current systems is usually the same as that used for primary distribution when the latter is below 15,000 volts, although steam turbo-alternators are often provided with raising compensators having a ratio of 1 to 2 when the line voltage supplied is in the range from 6000 to 15,000. In most systems of small and medium capacity the a-c. line voltage is 2300. The secondary distribution system is supplied by transformers and is usually at 110 to 115 volts between lines.

Small self-contained lighting outfits for train-lighting and similar service where a storage battery is used for regulating purposes are usually designed for a voltage range from 25 to 35 or from 50 to 65, and use lamps of the train-lighting and compensator types. See also *Lighting of Trains by Electricity*.

Phases. — The polyphase system affords distinct advantages in the first cost and voltage regulation of both generating equipment and lines. Primary distribution in all modern a-c. systems is either 2-phase or 3-phase, the latter predominating largely. Secondary distribution from transformers is either single-phase, 2-wire or 3-wire; 2-phase, 3-wire or 4-wire; or 3-phase, 3-wire or 4-wire. 6-phase connections are used only as a link between high voltage systems and synchronous converters. See also *Converters, Synchronous; Transformers*.

Frequency. — The standard lighting frequency in America is 60 cycles, and that in Europe 50 cycles. A frequency of 25 cycles has many advantages for overhead transmission and for conversion to direct current by synchronous converters. Power transmitted at 25 cycles is frequently converted to 60 cycles for lighting purposes by the use of frequency changing motor generators. In a few cases where a large load of induction motors is associated with a lighting system the compromise frequency of 40 cycles is employed. The performance of arc lamps and of incandescent lamps for interior lighting is not satisfactory below 40 cycles, due to an obvious and annoying flicker.

PRIME MOVERS. — (*See also Gas Engines; Steam Engines; Steam Turbines; Water Wheels.*) Prime movers for lighting plants should provide approximately constant speed without variation in angular velocity during each revolution. The steam turbine has a great advantage over the reciprocating engine for large alternators, due to its lower first cost and superior operating

economy. It has marked incidental advantages due to lighter foundations, smaller space requirements, elimination of fly-wheel, ease of attendance, and lower cost of maintenance. The piston engine is preferred for the driving of direct-current generators, because of its more appropriate speed.

Internal combustion engines surpass steam power in thermal efficiency, but are handicapped by higher first cost and small range of overload capacity. Their net advantage over steam power may be large when the cost of coal is very high, when a supply of natural or by-product gas is available at low cost and when the load factor of the system is unusually good. Internal combustion engines do not compete successfully with steam units in plants furnishing both heating and lighting service where a supply of exhaust steam has large value.

The crude-oil engine involves a high investment and heavy maintenance expense, but is in other respects an excellent type of motive power where oil is a more economical fuel than coal. Gas from a public source of supply and gasoline are used to a large extent in very small lighting plants to operate internal combustion engines. They are relatively expensive fuels, but may afford a saving by displacing a gas-producing plant on the premises. Gas-engines in lighting plants should be controlled by close-regulating governors and should be supplied with fly-wheels of considerable inertia.

Waterwheels of all types are well adapted to the driving of lighting generators if controlled by close-regulating governors.

Overload Capacities. — Steam prime movers are capable of carrying continuous overload capacities of 50 per cent or more whereas gas engines and waterwheels are very limited in this respect. A large overload capacity enables a plant to carry a smaller reserve equipment for emergencies. Current practice favors the use of a sufficient boiler or gas producer capacity to carry the average load with high efficiency and resort is had to forcing during peaks of short duration. In the average of a large number of modern stations of medium capacity 0.4 boiler horse-power is provided for each kilowatt of generating capacity.

GENERATORS. — (*See also separate articles on Generators.*) Direct-current generators are usually compound-wound and are operated at the voltage of the distributing system. A heavy direct current can usually be more economically secured by the conversion of alternating current than by direct generation. This method is an economic necessity when the direct-current load is more than one mile distant from the station. Edison 3-wire systems may be supplied by sets of two generators in series, by special 3-wire generators or by standard 2-wire generators operated in conjunction with voltage balancing sets.

Polyphase alternating-current generators are chosen for low cost and good regulation. Small low-speed alternators are usually provided with individual exciters, often on the same shaft, but large alternators are supplied with exciting current from a central system comprising several exciters in parallel.

Constant-current d-c. generators are now practically obsolete. Power for series circuits is now most economically obtained from constant-potential a-c. generating sources through constant-current transformers. Direct current for series circuits is obtained by operating the mercury arc rectifier in series with the secondary circuit of the constant-current transformer.

DISTRIBUTION. — (*See also Distribution and Transmission Systems.*) Distribution systems are designed with a view to the greatest possible reliability of service and the closest regulation of voltage consistent with reasonable investment. The 3-wire system is standard for local d-c. service. An interconnected network of mains is used in extensive 3-wire systems and is fed at many points by feeders from stations or substations. Alternating current is distributed at 2300 volts or more, 3-phase, to transformers, from which secondary distribution is made to consumers by 2-wire and 3-wire systems. To obtain good voltage

regulation on polyphase systems it is necessary to maintain a close balance of loads.

SUBSTATIONS. — (*See also Substations, Lighting.*) Substations are used for the following purposes: (*a*) to receive alternating current from high voltage transmission lines or feeders and reduce it in voltage for local distribution; (*b*) to convert alternating current from feeders into direct current for use in the adjacent territory; (*c*) to convert alternating current received from feeders at 25 cycles to 60 cycles for distribution by local lighting circuits; (*d*) transform alternating current from constant potential sources to constant current, either direct or alternating, for the supply of arc lighting circuits; (*e*) to house storage batteries used as load regulators or reserves on d-c. systems; and (*f*) to house feeder regulators for the control of voltage on lighting circuits. Conversion to direct current is accomplished either by motor-generator sets or by synchronous converters. Motor-generator sets may be either of the synchronous or the induction type and are usually operated without step-down transformers. Synchronous converters are usually 3-phase or 6-phase and are always associated with voltage-lowering transformers. Converters may be of the split-pole type, the synchronous booster type or the compound type to provide automatic control of d-c. voltage, or may be operated in conjunction with voltage regulators similar to those used on a-c. feeders.

Motor Generators versus Synchronous Converters. — (*See also Motor Generators; Converters, Synchronous.*) Motor-generator equipment is more expensive and less efficient than converter equipment, but occupies less space, affords more synchronous condenser capacity for power factor correction and is more reliable in its operation, especially at an a-c. frequency of 60 cycles. Synchronous converters are used almost exclusively for 25-cycle conversion and are gaining in use at 60 cycles. Each converter is usually supplied with its own bank of lowering transformers. Converters of larger capacity than 500 kw. are usually operated 6-phase. Converters supplying 3-wire d-c. systems are adjusted to give from 220 to 250 volts, d-c., and the neutral wire is derived from the neutral connection of the transformers.

Storage Batteries. — (*See also articles on Batteries, Storage.*) Storage batteries are extensively used in stations and substations as a reserve against the failure of the primary source of direct current. It is difficult to operate the battery as a load regulator on constant-voltage systems, especially by a floating connection. A booster or end-cell arrangement is required to compensate for the sloping volt-ampere characteristic. The substation battery commonly floats on the bus bars fully charged and assumes the load if the voltage of the bus bars falls a certain amount. The battery falls in voltage as its discharge proceeds and additional cells must be added in series to sustain the line voltage. The end-cell switch for this purpose may be either hand-operated or automatic. If automatic, it is controlled by a relay switch operated by a solenoid connected across the main bus bars.

PROTECTIVE EQUIPMENT. — (*See also Switchgear Equipment for Power Stations; Lightning Protectors.*) As lighting systems are required to render practically uninterrupted service the protective appliances are intended to disconnect apparatus and circuits only in extreme emergencies and then only those in serious danger. Generators and exciters are not as a rule provided with automatic circuit breakers. Radial feeders and transmission lines have circuit breakers which open with extreme overloads, often with inverse time elements. Feeders and transformers operated in parallel at both ends are provided with selective relays which open the circuit breakers at both ends in case of trouble, and so prevent the disturbance of other circuits.

VOLTAGE REGULATION. — Aside from the condition in which the illuminants are installed and maintained, the quality of lighting service is almost solely a matter of continuity of service and close regulation of voltage. The best service standards require that the variation of voltage at the lamps shall at no time exceed 2 per cent on either side of the mean. Service with less than 3.5 per cent variation may be considered fair and with more than 5 per cent decidedly poor.

In direct-current systems fairly constant voltage at the loads may be obtained by the use of generators properly over-compounded. A much more sensitive method of control is afforded by the Tirrill regulator (*see Regulators*), which automatically corrects all but the most transient voltage fluctuations of the generators. Synchronous converters have fixed ratios of voltage conversion, but may be regulated to provide approximately constant voltage at load centers by methods cited above in the paragraph on *Substations*. A plan of voltage regulation commonly used in 3-wire networks is to provide in the station or substation two sets of bus bars differing somewhat in voltage. All feeders terminate in selector switches, by which they may be connected with either set of bus bars as desired. The more heavily loaded feeders are connected to the higher bus, the others to the lower bus, with the result of nearly uniform voltage throughout the network of mains.

The following voltage-control methods are employed in a-c. systems: (1) to regulate all generators by hand or by Tirrill regulators to constant voltage or to a voltage rising in proportion to the load; (2) to provide not only approximate regulation of generators but to equip each outgoing line with feeder regulators of the switch or induction type, to be automatically controlled if desired, so that each feeder is caused to supply approximately constant voltage at its center of load. The latter system is the more flexible and economical for extensive distribution systems, since each feeder is independently regulated and may be proportioned in cross-section with regard to economy rather than inherent voltage regulation. Single-phase regulators are preferred for close control if the loads are subject to unbalancing.

As checks on voltage regulation at load centers voltmeters should be provided at stations or substations to indicate conditions at these centers. The voltmeters may be connected to the feeders at the distributing centers by small pressure leads or to the feeders at the station through compensators which allow for the voltage drop in the feeders. When a power load of low power factor is associated with an a-c. lighting system, voltage regulation and economy in transmission can often be assisted by the use of the synchronous condenser to compensate the lagging current; see *Converters, Synchronous*.

[W. E. Wickenden.]

LIGHTING OF TRAINS BY ELECTRICITY. — (*See also Batteries, Storage, Alkaline and Lead Types; Generators, Direct-current.*) The electric lighting of railway trains on steam lines has become a very important industry. According to H. A. Currie and B. F. Wood, whose comprehensive paper is the basis of this article, there were in use or contracted for on June 30th, 1912, a total of over 15,000 cars lighted by electricity on the railways of the United States and Canada.

Systems Used. — Three systems are in general use, which are known as the straight storage system, the head-end system and the axle generator system. In the straight storage system, each car is provided with a storage battery which must be charged at terminals during the lay-over period. The head-end system consists essentially of a steam-driven generator located on the locomotive or baggage car and with connections through the various cars. The axle generator system, which is rapidly superseding the others, consists of a generator belted to the axle of each car, a storage battery for supplying current when the speed of the cars falls below a certain value, a regulator device for controlling the generator output and voltage at all train speeds, and a regulator for controlling voltage on the lamp circuits. Each of these systems is described in detail below.

Standard Lamp Voltages. — The standard lamp voltage was 60 volts for all three systems when carbon lamps were used, but it has been changed in the axle generator system to 30 volts since the introduction of tungsten lamps. The usual lamp is a 25-watt drawn-wire filament tungsten lamp with a round bulb, although lamps of 10, 15, 20, 25 and 50 watts are available for this service. The standards of the Association of Railway Electrical Engineers are accepted as representing the best American train-lighting practice.

Limiting Size of Battery. — The batteries in general use in train-lighting service have a rated capacity of approximately 300 ampere-hours. This is about the maximum limit of capacity for Planté type batteries having weight low enough for convenience in handling.

STRAIGHT STORAGE SYSTEM. — In this system, each car is provided with a storage battery, which must be charged at terminals during the lay-over period. The fundamental requirements are:

1. The capacity of the battery must be in excess of the demand for current to operate lamps, fans, etc. for the longest run between charging periods.
2. The power plant, or other outside source of power, must be of sufficient capacity to meet the maximum demand for charging current.
3. The lay-over time at terminals must be sufficient to cover all necessary shifting and charging of the batteries at the proper rate.
4. The yard must have a sufficient number of tracks provided with charging outlets, so arranged that the charging of batteries will not interfere with shifting operations.

Battery Equipment. — The great majority of cars on which this system is used are equipped with a 64-volt lead or nickel-iron battery with cells connected in series. A few cars are operated at other voltages, viz. 26, 30, 32 and 110.

Two battery boxes are generally provided for 64 volt batteries and secured to the under side of the car, one on each side equidistant from the ends of the car, and with the front or door side slightly back of the line of outside finish. The cells are put up in double compartment lead-lined wood tanks provided with handles, rollers, etc. for convenience in handling. The two halves of the battery are connected in series and leads are run to the switchboard in the end of the car.

Taps are taken off these leads at the battery terminals and run to charging receptacles, conveniently located on each side of the car.

Charging of Batteries. — The charging voltage provided is usually 50 per cent higher than the normal voltage of the battery. Hand or automatically operated resistance devices, usually carbon rheostats, are provided for reducing the voltage of the individual charging lines to the proper point. The batteries are charged while on the car under normal conditions. When the lay-over period is short it is sometimes necessary to exchange a discharged battery for one fully charged.

HEAD-END SYSTEM. — This system requires the following apparatus:

1. A generator, usually steam turbine driven, placed in the baggage car or on the locomotive, and furnished with steam from the locomotive.

2. The necessary indicating, regulating and controlling apparatus placed near the generator and in an accessible position.

3. Train line wires of the proper size on each car and running the entire length of the train, flexible connections being made between cars, in the vestibule.

4. Batteries, consisting of a suitable number of cells connected in series and placed in battery boxes attached to the under side of each car.

5. Lamp regulators are sometimes installed in the cars to compensate for the line drop and to maintain constant voltage at the lamps.

Head-end systems are generally operated at 64 or 110 volts, although the introduction of tungsten lamps has to a great extent eliminated the need of the high voltage equipments, and comparatively few railroads are now using 110 volts.

Another system has a 64 volt 200 kw. axle-driven generator mounted on the baggage car truck but projecting into the car body. It is operated through a chain drive.

Requirements for Successful Operation. — The successful operation of this system requires that:

1. A sufficient amount of steam at the proper pressure be provided when lighting is necessary. As it is the object of the transportation department to get trains to their destination on time, lack of steam is felt first by the lighting system, the pressure being reduced or steam cut off entirely so that the schedule may be maintained.

2. When the train is broken en route, each section must either be equipped with a battery to insure light until the train is again made up, or provided with some auxiliary light.

3. A member of the train crew must be capable of operating the generating apparatus and of making running repairs and adjustments en route.

AXLE GENERATOR SYSTEM. — The axle generator systems used in this country comprise the following principal parts:

1. An axle-driven generator mounted on the car truck. (Abroad where rigid trucks are used the axle generator is frequently secured to the under side of the car body.)

2. A suspension by which the axle generator is supported from the truck frame.

3. A drive, connecting the armature shaft to the axle.

4. A regulator for controlling the voltage and output of the generator at all train speeds.

5. An automatic switch designed to open on reverse current for the purpose of preventing discharge of the battery through the generator.

6. A regulator for controlling the voltage impressed on the lamp circuits.

7. A battery of a suitable number of cells to supply current when generator current is not available.

Three European systems which do not require complicated regulator mechanisms are being introduced into the United States.

Requirements for Successful Operation. — For the successful operation of the system, the following requirements must be met:

1. The polarity of the generator terminals must remain unchanged with a movement of the car in either direction.

2. At all train speeds, from the cutting-in speed of the generator to the maximum, the generator output and voltage must be maintained within the desired working limits.

3. The generator must be automatically connected and disconnected from the battery circuit as the train speed rises above or falls below the critical range of speed.

4. The lights may be burned at any time and the transfer of this load from the battery to the generator and vice-versa must result in no appreciable change in the candle power of the lamps.

5. The voltage impressed on the lamp circuit must be maintained within such limits as will give satisfactory illumination and reasonable life of lamps.

Suspension of Generator. — In this country it is general practice to support the axle generator from the truck frame. When first applied, the generator was placed between the axle and the truck end sill, this arrangement being known as "inside suspension." The generator was not easily accessible for inspection and repairs, and at the present time it is placed outside of the truck frame, this arrangement being known as "outside suspension." There are four general methods of carrying the generator from the suspension framing, viz. bottom pivoted, top pivoted, parallel link and sliding. The bottom pivoted was first used but at the present time the parallel link suspension is in more general use.

Transmission. — The most usual form of transmission for axle generators consists of a rubber-filled canvas belt running on pulleys on the axle and the armature shaft. The axle pulley as first used was cast iron mounted directly on the car axle, the bore of the pulley conforming to the taper of the axle, but on account of inequalities in the axle which was hammered or rough-turned, it had to be wrapped with tarred paper. The axle pulley at present in use is of pressed steel, mounted on a steel bushing, the bushing being secured independently to a turned seat on the axle, and the pulley mounted thereon. Belt-tension is provided by means of springs which also afford relief to the belt due to the movement of the car axle with respect to the truck frame. One spring is generally used when the generator has top, bottom or sliding suspension and two springs with the parallel link suspension. Chains of the silent type have also been tried and have the advantage of positive action and decrease in bearing pressure, but the wear of the links both on the face and the pivot sprockets has been excessive. Belts of V section have been tried and would seem to have the same advantages as the chains, but it is found that in winter the bottom of the V groove in the sheaves packs with ice and snow, and driving power is lost. Neither the chain nor V belt requires tension device.

Lubrication. — The generator bearings are a great source of trouble, and some method of lubrication is required which will confine the oil in the bearings under the severe conditions of service to which these machines are subjected. Ball bearings have been very successful when used with grease free from acid or alkali, which does not oxidize, evaporate, become gummy or lose its body.

Method of Controlling Voltage and Current. — The usual modern regulating mechanism keeps the current output of the generator constant regard-

less of the demand as long as the battery is not fully charged. As the battery becomes charged, the generator voltage gradually increases and at a predetermined voltage, a change in control is effected whereby the current is caused to decrease until the battery is floating on the line. When the speed of the train (and therefore the generator voltage) falls below a predetermined value the generator is cut out of circuit and the lamps receive their current from the battery.

As the voltage on the battery on charge is approximately 30 per cent higher than on discharge, it is necessary to provide some means of lamp regulation in order to keep a constant voltage on the lamps. This is accomplished by means of a regulating resistance, a series of carbon blocks, the resistance being varied by varying the pressure on these blocks, the variation of pressure being determined by a pilot voltage coil connected across the lamp mains. (The preceding part of this article is abstracted from H. A. Currie and B. F. Wood, *Trans. A.S.M.E.*, 1912.)

Costs. — The cost of axle lighting includes the following items: fixed charges on equipment, maintenance, depreciation, haulage and energy. The first cost and maintenance cost of axle-lighting equipments are given in the following table.

Type of car	Kw. rating of generator	First cost including battery, dollars	Maintenance cost per car, dollars	
			Per 1000 miles	Per month
Baggage................	1	600	0.70–0.75	5.00– 5.50
Passenger coach or Sleeping car............	2	1000	1.50–2.25	10.75–16.00
Dining car.............	3	1200	4.00–5.00	31.50–40.00

The cost of hauling an increment of weight of the order of magnitude of axle-lighting equipments is about one mil per ton-mile. The energy supplied to the lighting generator costs about one mil per rated kilowatt capacity per mile. The depreciation should be figured on the cost of equipment less that of the battery renewals which are included under maintenance. No reliable data exist as to the relative cost of operating axle generator and other systems.

LIGHTNING PROTECTORS: GROUND WIRES, ARRESTERS, CHOKE COILS. — (*See also Distribution Lines; Ground Connections; Power Stations; Substations; Switch Gear Equipment for Power Stations; Transmission Lines.*) Abnormal rises of voltage in transmission and distribution circuits may be set up either by lightning discharges or by electrical oscillations caused by switching loads on and off the lines. The latter type of disturbances have been called "internal lightning." High-frequency oscillations are usually of small power and are generally called "statics." The term "surge" is used for any kind of oscillation.

A "ground wire" is a grounded wire which is run above and parallel to the main wires of an aërial line. A "lightning arrester" is any device shunted between wires or from wire to ground, which device under normal voltage permits practically no current to flow, but which becomes a fairly good conductor, usually by the formation of an arc, when the voltage rises a given amount above normal. A "choke coil" is a coil of wire of comparatively low resistance and small inductance, which is placed in series with the line. The coil has a very small impedance to normal line frequencies, but a high impedance to high-frequency oscillations.

GROUND WIRES. — A line completely inclosed in a grounded metallic sheath, as, for example, a lead-covered cable, is completely protected from induced electrostatic charges (*see Electricity and Magnetism, Principles of*). The ground wire used over aërial transmission lines acts as a partial screen and is one of the best means of protecting aërial lines against lightning. The protection is not perfect, however, since the wire forms only a partial screen.

Where systems operate with a thoroughly grounded neutral this neutral wire can form the overhead grounded conductor and the system becomes practically a three-phase four-wire system allowing the use of single-phase transformers of 58 per cent normal line voltage to be connected between any phase wire and the neutral. See articles on *Distribution Circuits; Transmission Lines.*

LIGHTNING ARRESTERS. — A lightning arrester consists essentially of a spark gap so set that excess voltage will cause the gap to arc over, allowing the charge due to this voltage to pass to ground. There is combined with the gap some means of suppressing the power arc which follows and which tends to continue after the abnormal voltage has ceased.

An ideal lightning arrester should take no current at the ordinary operating potential, but at any potential much higher than ordinary there should pass enough current to limit the abnormal potential to some fixed safe value. When the abnormal potential ceases the arrester should stop taking current from the line. The closer an arrester approaches these ideal conditions the better the arrester.

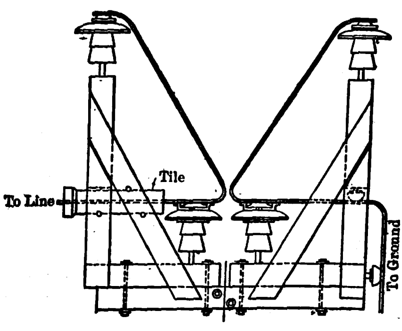

Fig. 1. Horn-gap Arrester

Horn-gap Arrester (Fig. 1). This arrester consists of two knee-shaped horns mounted on regular line insulators. The distance between the knees depends largely upon the voltage between line and ground, and varies from about 1/16 in. to 3/32 in. for 2200

volts to about 6½ in. to 9⅞ in. for 110,000 volts. One of the horns is connected directly to the line and the other through a resistance, usually water, and a choke coil, to the ground. Practice differs as to whether the water should have salt added, but it should always be covered by a layer of oil about one-eighth inch deep to prevent evaporation.

The operation of the horn gap is based on the fact that a short-circuit once started at the base travels upward due to the heated gases and to the force exerted on the arc by the magnetic field of the current until the arc is ruptured by attenuation. On circuits of high voltage this rupture sometimes takes a second or two, but seems to act with but little disturbance of the line. The angle between the horizontal and the straight portion of the knee ranges from 55 to 60 degrees. The curvature of the knee should have a radius of from 3 to 5 inches.

Multipath Arresters have been developed for a-c. and d-c. service for voltages not exceeding 1000 by the use of a carborundum block fastened between two terminal plates, thus allowing the static discharge to spread itself over a number of minute discharge paths. The normal voltage between the line and the ground is divided into so many minute gaps that the voltage across each gap is too small to maintain an arc after the discharge has passed.

Nonarcing Arresters (Fig. 2) based on the discovery of "nonarcing metal" by Mr. A. J. Wurts, formed the first successful high-voltage arresters. The peculiar property of this metal is that an alternating current will not maintain an arc between adjacent cylinders of the metal provided the voltage is not too high and that the power current which follows the lightning discharge does not vaporize too much of the metal. The first condition is met by having a fairly large number of very small gaps in series, and the second condition gives no trouble where the amount of power current is comparatively small as was the case on the early high-voltage installations. For large amounts of power it becomes necessary to use resistances in series with the spark gaps to limit the current, and these resistances reduce the effectiveness of the arresters. For very high voltages different schemes are used to reduce the number of gaps required. It has been found that by shunting a certain number of these gaps by a non-inductive resistance the effectiveness of the arrester is increased.

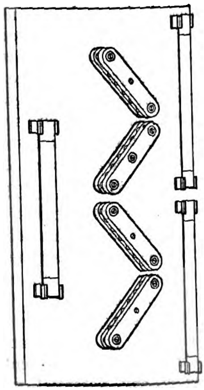

Fig. 2. Nonarching Lightning Arrester

Fig. 2 shows an arrester of this design intended for service on 6600-volt lines where the capacity does not exceed 2000 kv-a. The nonarcing cylinders are held between porcelain insulators in such a way that there is an air gap of about 1/32 inch between adjacent cylinders in each one of the four sets of seven cylinders. The marble slab forming the base of the arrester also has mounted on it three graphite resistance rods shunting some of the gaps. Modifications of this scheme were used for the "low equivalent," "multigap," "multiphase" and similar "shunted gap" arresters that were installed before the electrolytic arresters were brought out and are still giving good satisfaction in many plants operating at voltages as high as 88,000 volts.

Electrolytic Arresters (Fig. 3) have been found after experimental research and operating experience of many years to be the best suited for high voltages up to the highest in actual service. See also *Power Stations, Hydroelectric.*

These lightning arresters are usually provided with a horn-gap device mounted on a framework and arranged so that the length of gaps can be adjusted easily while the breaker is in service. The arrester itself consists essentially of a system of nested aluminum cup-shaped trays as shown in Fig. 3, suitably supported and arranged in a steel tank containing a liquid electrolyte which forms insulating films on the surfaces of these trays. These films prevent passage of current at normal voltages and break down at abnormal voltages; on the cessation of the abnormal stress the film regains its original resistance. When these arresters are arranged for outdoor service, the aluminum trays filled with electrolyte are completely immersed in transformer oil contained in the steel tanks. This oil provides an insulation and cooling medium, and prevents evaporation of the electrolyte. The volume of oil in the tanks, which are nearly filled, is great enough to absorb the heat due to a continuous discharge for a long period.

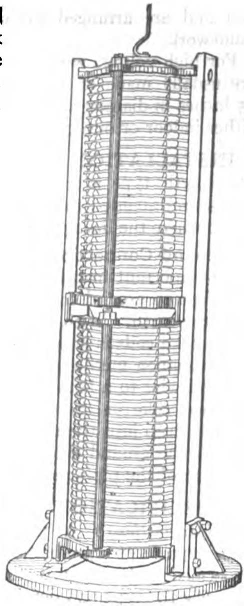

Fig. 3. Column of Aluminum Trays for Electrolytic Arrester

It is usually necessary to charge the arrester periodically for the purpose of maintaining the film of oxide on the aluminum plates. The horn gaps are readily adjustable so that in one position the line current will arc across the gaps and charge the cells. In a second position the gaps are so set as to discharge only at a predetermined point slightly above the operating voltage. In the third position of the horn gaps, the gap is so large as to prevent the possibility of arcing across and in this manner acts as a disconnecting switch when it is necessary to inspect the tanks containing the electrolytic cells. See also *Power Stations, Hydroelectric.*

CHOKE COILS (Fig. 4) are an important element in the protection of circuits against static disturbances, in addition to the lightning arrester itself. The inductance of the choke coil acts as a reflector to high-frequency waves and prevents the potential to which the leads of the generator or transformer coil are subjected from undergoing excessive or abrupt changes. As at the operating frequency the value of volts per turn in a choke coil is very small, a surge may cause a spark to pass momentarily between turns but no arc will be formed. This is not usually true of a generator or transformer. Although extra insulation for the end turns of generators and transformers is desirable, it cannot entirely take the place of choke coils but frequently permits the use of coils of a smaller choking power.

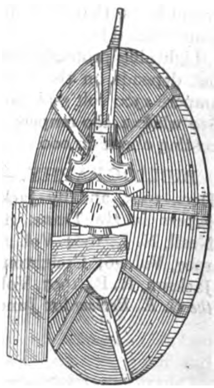

Fig. 4. Choke Coil

Fig. 4 shows a type of choke coil built in normal capacities up to 260 amperes at 25,000 volts. These coils are made by winding wire or copper strap on circular or elliptical center blocks with heavy insulation between turns. The coils are without

iron and are arranged for mounting on the station wall or on a suitable framework.

For high-voltage work one or more open helical coils are used. These coils are usually made of aluminum wire wound in a helix of about 20 turns and 15 inches in diameter. They are arranged for supporting on insulators and for either indoor or outdoor mountings.

INSTALLATION OF ARRESTERS is dependent on their design. The electrolytic type is frequently made suitable for outdoor service; the other types are intended to be mounted indoors and are connected in circuit at the point where the lines pass from the building.

Ground Connection. — (*See also article on Ground Connections.*) One of the most important features of a lightning-arrester installation is the securing of a satisfactory ground connection to enable the static electricity to pass readily into the earth. With a poor ground connection the value of lightning arresters and choke coils is greatly reduced.

A common method of securing a ground connection is to solder or rivet the ground wire to a large tinned copper plate which is buried in several layers of crushed coke or charcoal in permanently damp earth. Wrought-iron pipes driven deep into the moist earth will also make a good ground. In hydraulic plants the ground should include a connection to the penstock or some other portion of the piping system.

SPECIFICATION FOR LIGHTNING ARRESTER. — (*See also article on Specifications.*) As the services to which lightning arresters are subjected are not capable of reproduction for testing purposes, lightning arresters cannot be specified in terms of performance. Hence it is necessary for the engineer to specify the type and details of construction after an examination of the various types. When calling for proposals, the following details should be stated: station or out-of-door service, voltage and frequency of circuit; details as to where arresters are to be located.

DIMENSIONS, WEIGHTS AND COSTS vary so much for the different voltages, class of service, whether grounded or ungrounded neutral, indoors or outdoors, that it is impossible to tabulate this information in the limited space available.

Lightning protection in a power house is almost independent of its capacity but depends on the voltage and number of feeders to be protected. A 200 ampere 2300 volt 3-phase feeder would require lightning protection costing about $20 while a 200 ampere 110,000 volt feeder would require lightning protection costing about $2,000.

[S. Q. HAYES.]

LOCOMOTIVES, ELECTRIC. — (*See also Cars, Electric; Collectors, Current; Locomotives, Steam; Railways, Energy Requirements and Motor Capacity for.*) For many years a new type of electric locomotive was designed for nearly every new proposition. However, with the very numerous applications of electric locomotives of from 30 to 50 tons weight for slow freight and switching service on interurban roads and in terminals, the double-truck bogie type finally demonstrated its superior fitness and came to be adopted almost universally in America for all work involving speeds less than 45 m.p.h. For higher speeds special provision must be made for guiding the locomotive around curves by the addition of guiding trucks or axles, for placing as much of the weight of the motors as possible on springs and for raising the center of gravity to a reasonable height (five feet or over). With a low center of gravity every sidewise movement of the mass of the locomotive strikes a blow side-wise on the track, but with a high center of gravity a side swaying is transformed into a downward thrust on the track. As the track is not usually designed to withstand great side thrusts it is better to avoid a low center of gravity in high-speed locomotives.

The coefficient of adhesion for electric locomotives has usual and safe values of from 18 to 22 per cent. It is higher for electric than for steam locomotives on account of the uniform torque of the electric motor. With clean dry rails the coefficient for electric locomotives may be as high as from 30 to 40 per cent.

CLASSIFICATION. — Locomotives are usually classified by the arrangement of their wheels and the subdivision of the wheels into driving wheels and guiding wheels. A series of numerals is used, each numeral representing a group of wheels of one form usually on one truck. Thus 4–4–0 designates a locomotive having four wheels on a guiding truck, four driving wheels connected and no trailing wheels or truck. This is the common "American" type of steam passenger locomotive. An ordinary double-truck four-motor freight locomotive or motor car would be designated as 4–0–4. (*See also Locomotives, Steam.*)

TYPES OF MOTORS.— Locomotives are built with various types of motors and operate from various systems of electrical distribution, e. g.,

a. Direct-current Motors at 600, 1200, 1500 or 2400 volts; for the higher voltages two motors are operated in series.

b. Single-phase Motors for 250 volts and 15 or 25 cycles, connected to the secondary of a transformer which receives its power from a 6000- or 11,000-volt trolley line.

c. Three-phase Induction Motors operating at about 500 volts supplied by the secondary of a transformer whose primary is connected to a 6000- or 11,000-volt three-phase trolley.

CONTROL SYSTEMS. — The control of all modern electric locomotives is by the multiple-unit system (q.v.), as the currents required are too large or the voltage too high for a drum control (q.v.). The possibility of one motorman operating and controlling two or three locomotive units at the same time is also advantageous.

TYPES OF ELECTRIC LOCOMOTIVES.— The simplest form of electric locomotive is a box car with a motor geared to each of the four axles on two bogie trucks. Such a locomotive would be geared for a very low speed and hence high tractive effort. To prevent slipping of the wheels the car would be weighted down with ballast or a load of freight.

The most common type of electric locomotive consists of a cab and framing carried on two heavy four-wheel trucks, each axle carrying a geared motor. Extra strength is provided in the cab framing to transmit the tractive effort of

the motors to the couplers. The complete locomotive may weigh from 30 to 50 tons and is equipped with motors having an aggregate capacity of approximately 500 horse-power. It will haul trains of about 20 cars, weighing about 500 tons, at speeds from 20 to 30 miles per hour. The usual tractive effort at the one-hour rating of the motors is from 10,000 to 15,000 lb. Such locomotives are well adapted for switching purposes in terminal freight yards and for hauling freight trains on interurban electric railways.

Detroit River Tunnel Locomotives. — A further development of this type of locomotive is exemplified in the large locomotive used for pusher and grade service in the Detroit River Tunnel of the Michigan Central R.R. and other similar installations. Each of these locomotives weighs from 100 to 120 tons, all on drivers, and consists of two four-wheel trucks carrying geared motors of from 300 to 500 horse-power each. The two trucks are coupled together by a pin or hinge which causes them to guide each other. This is called the "Articulated" type. The cab, containing all the control and auxiliary apparatus, is mounted on the trucks. The Detroit River Tunnel locomotives operate on 600 volts d-c. Locomotives of this type are now in operation also on 2400 volts d-c. and on 6000 volts three-phase a-c. They are limited in speed to about 40 miles per hr. on account of their lack of guiding trucks.

New York Central R.R. Locomotives. — The locomotives constructed in 1910 have a leading and a trailing two-axle guiding truck and in the middle four driving axles with gearless motors. The armature of each motor is mounted directly on the driving axle and the bi-polar field of the motor forms a part of the mechanical frame work of the locomotive. The magnetic flux passes through all four motors in series and returns by the side frames. The motors are wound for 600 volts d-c. and have very large air gaps to allow for the play between the armature and the field as the wheels pass over irregularities in the tracks. The field structure is spring borne but the armatures are not.

The locomotives constructed in 1913 consist of two sections articulated, with two two-axle trucks on each section. One truck on each section is rigid and the other is a bogie or guiding truck. Every axle carries a motor and all wheels are of the same size. The single cab is carried on a king pin on each section.

New Haven R.R. Locomotives. — The type of electric locomotive adopted by the N. Y., N. H., & H. R.R. in 1911 has four gearless single-phase series motors, the armatures being mounted on quills concentric with the driving axles and driving the wheels by means of springs. The locomotive has two trucks, each having four large driving wheels and two smaller guiding wheels. The motors are designed to operate at from 250 to 300 volts either a-c. or d-c., two in series on the line for d-c. and on the secondary of a transformer for a-c. The line voltage is 11,000 at 25 cycles.

Pennsylvania R.R. Locomotives. — The locomotives of the Pennsylvania R.R. consist of two similar units coupled back to back. Each unit has a two-axle guiding truck and has two driving axles rigid with the body frame. There is one large motor per unit, mounted in the cab and driving the wheels by means of an inclined connecting rod from the motor to a jack shaft and horizontal side rods from the jack shaft to the drivers. The connecting rods on opposite sides are placed at right angles to avoid dead centers.

SPECIFICATION FOR ELECTRIC LOCOMOTIVE.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

On important high-speed systems it is usual for the design of the locomotive to be worked out by the purchaser and manufacturer working in collaboration,

* By W. A. Del Mar.

and in such cases, the design is usually specified in detail. In other cases, it is more usual to specify the operating characteristics and leave the design to the manufacturer. The following memoranda are to assist in the preparation of a specification of the latter type.

General Description of Service. — Whether for direct- or alternating-current, single-phase or three-phase, freight or passenger hauling, overhead trolley or third rail. Line voltage, etc.

Specific Details of Work to be Performed by Locomotive. — Weight of cars loaded and empty. Maximum train weight. Average train weight. Time to make typical run of stated length. Number and duration of stops in typical run. Ton miles per day per locomotive. Maximum speed on level with average load. Maximum speed on maximum grade with maximum load. Acceleration (miles per hour per second), with maximum load. Hours per day in regular service. Amount of time in shifting and yard service.

Profile and Plan of Line. — Grades and curves.

Clearances and Limiting Dimensions.—Gauge of track, clearance diagram of right-of-way. Maximum and minimum height of trolley wire or third-rail location. Height of coupler. Wheels, tread and flange (M.C.B. or special). Weight of rail. Minimum radius of curve. Wheel diameter. Maximum permissible weight per running foot of right-of-way.

Operating Characteristics. — Absence of nosing or lateral swing. Absence of rail pounding. Temperature-rise limitations. Efficiency.

Control. — See specifications under *Control Systems for Railway Motors*.

Motors. — See specifications in articles on *Motors*.

Air Brake. — Straight, automatic or combined. General characteristics.

COST, WEIGHT AND DIMENSIONS. — Electric locomotives cost about $400 per ton weight, which is considerably more than steam locomotives, but they are cheaper to operate and maintain as they can make more mileage per day. It costs, roughly, between 5 and 10 cents per locomotive mile to operate electric locomotives.

The characteristics of the most prominent types of electric locomotives are given in the following table:

CHARACTERISTICS OF ELECTRIC LOCOMOTIVES

Item	Bush terminal	Piedmont R.R.	Butte A. & P. R.R.	Detroit River Tunnel

[W. I. SLICHTER.]

LOCOMOTIVES, STEAM. — (*See also Locomotives, Electric; Railways, Energy Requirements and Motor Capacity for.*) Locomotives are classified broadly by the number of truck and driving wheels. Each arrangement of wheels has a definite name but the various wheel arrangements have multiplied so rapidly of late that the "Whyte classification" has largely come into use.

Whyte Classification. — According to this scheme of classification three numbers are used; the first indicates the total number of leading or truck wheels in front of the drivers, the second indicates the total number of drivers, and the third indicates the total number of wheels behind the drivers and under the locomotive proper. Tender wheels are not included. This classification may be extended, by the use of more than three numbers, to cover engines of the articulated, or Mallet, type. The classification and names of some of the more important types are given below, the weights being in short tons.

DESIGN AND PERFORMANCE. — A steam locomotive is essentially a moving power plant and as such it must transport its fuel and water with it. Its limitations as to size and weight are determined by roadway clearances, the curves upon which it must run, and the strength of the track supporting it.

The load upon a driving axle is generally limited to 30 tons. This weight is sometimes exceeded, but as a rule is not often equaled.

Maximum Power. — The limit of power of a steam locomotive is measured by the size and steam-producing capacity of its boiler (*see Boilers*). Owing to the necessarily small grate area, coal must be burned very rapidly under an induced draft. The rate of combustion is quite commonly as high as 100 lb., and is sometimes 150 lb. per sq. ft. of grate area per hour. The use of brick arches and superheaters largely increases the power, adding from 30 to 40 per cent in some cases. On account of difficulties of lubrication, wear of valves, etc., piston valves must be used with superheaters.

The maximum horse-power which can be exerted by a steam locomotive is in some cases 4000, although this is unusual; from 2000 to 2500 is a fairer maximum figure for ordinary cases. The largest tenders have a capacity of 9000 gallons of water and 15 tons of coal.

Tractive Effort. — The tractive effort of a single expansion steam locomotive at slow speed is computed from the following formula:

$$\text{Tractive effort} = \frac{P \times D^2 \times S}{d},$$

where P = mean effective pressure in cylinders, in lb. per sq. in. (usually taken as 0.8 of boiler pressure),

D = diameter of the piston, in inches,

S = stroke, in inches,

d = diameter of driving wheels, in inches.

Tonnage Rating. — By the tonnage rating of a locomotive is meant the weight, in tons, of the train which it can pull, exclusive of the weight of the locomotive, but including the weight of the tender. Short tons (2000 lb.) are used. Let:

F = maximum tractive effort, usually taken as the tractive effort corresponding to a mean effective pressure equal to 0.8 of boiler pressure,

G = maximum grade, per cent,

L = weight of locomotive, in tons,

R = locomotive resistance, lb. per ton,

r = train resistance, lb. per ton,

T = "tonnage rating," i.e., weight behind locomotive.

CLASSIFICATION OF STEAM LOCOMOTIVES

Type	Wheel arrangement	Name	Total wheels	Kind of service	Approximate weights,* tons, engine only	Load on drivers, tons per axle
0-4-0		4-wheel switcher	4	Switching	36	....
0-6-0		6-wheel switcher	6	Switching	83	....
2-6-0		Mogul	8	Freight	93.5	....
2-8-0		Consolidation	10	Freight	126	28
2-6-2		Prairie	10	Passenger & freight	122.5	28.3
2-8-2		Mikado	12	Freight	141	....
2-4-4		4-coupled double ender	10	Suburban	83	....

4-6-2		Pacific	12	Passenger & freight	158	33.5
4-6-4		6-coupled double ender	14	Suburban	78	....
0-6-6-0		Articulated	12	Freight	167.3	27.9
0-8-8-0		Articulated	16	Freight	222.5	27.8
2-6-6-2		Articulated	16	Freight	196	27
2-8-8-2		Articulated	20	Freight	231	25

* The weight of the tender loaded ranges from 58 to 92 per cent of the weight of the engine, the average being 74 per cent.

Then

$$T = \frac{F - (R + 20\,G)\,L}{r + 20\,G}.$$

See article on *Railways, Energy Requirements and Motor Capacity for*, for values of r and R. On heavy grades this value of the tonnage rating will be limited by the ability of the fireman to keep up full steam pressure.

Reduction of Tonnage Rating in Stormy Weather. — Weather conditions also affect the steam locomotive's capacity. The worst condition is cold weather with a heavy wind at right angles to the track. This side wind always makes engines steam badly and increases flange friction against the rails. It is a common cause of delays.

Tonnage ratings are reduced a variable amount under severe weather conditions. Some roads have fixed rules and some have not. The maximum reduction, taken from a table published in Bulletin No. 59 of the University of Illinois Engineering Experiment Station, is 30 per cent for temperature around 15 degrees below zero. On lines having heavy grades the grade resistance is such a large proportion of the total work to be done that the train resistance becomes a very small factor. Consequently the tonnage ratings for roads having very heavy grades are practically the same for all seasons and weather conditions.

Unbalanced Forces. — The necessity of partially balancing the heavy reciprocating parts by weights located on the wheels produces unbalanced vertical forces which are hard on roadbed and bridges.

Center of Gravity and Stability. — The boiler is necessarily placed almost wholly above the wheels and the center of gravity of the whole engine is therefore a considerable distance above the rails. Careful tests have shown this to be a positive advantage so far as ease of maintenance of track is concerned. By proper elevation of outer rails on curves, the overturning tendency of the centrifugal force may be wholly or sufficiently neutralized. This overturning tendency is much less than most engineers suppose. It is safe to state that it is impossible to *overturn* a locomotive at any practicable speed upon any ordinary curve by the action of centrifugal force unless the conditions are such (as in a cross-over, for instance) as to set up a rolling or oscillatory motion of the engine about its longitudinal axis. Generally speaking, the tender is the part of the train most likely to leave the rails. This is due to its varying and shifting load of coal and water.

Typical Large Locomotives. — The first three locomotives listed in the following table are perhaps the highest development of the steam locomotive up to the present date. The data for these locomotives, which are in use on the Pennsylvania R.R., was furnished through the kindness of T. R. Cook, Assistant Engineer of Motive Power, Pennsylvania Lines. These engines are all equipped with superheaters. The external heating surface of the superheaters is taken as 50 per cent greater than the heat surface of boiler in obtaining the total heating surface. In a test these locomotives produced an indicated horse-power of from 2 to 4 lb. of dry fuel per hour. The lowest rate represents a fuel consumption of 3500 to 4000 lb. of coal per hour, the locomotive having sufficient fire-box capacity to burn up to 9,000 or 10,000 lb. of coal per hour. This is a consumption of from 65 lb. to 180 lb. per sq. ft. of grate per hour.

The fourth locomotive is of the Mikado type, is not equipped with a superheater, and was built by the Philadelphia and Reading. It is designed to burn a mixture of buckwheat (anthracite) and soft coal. The information concerning this engine was taken from the Ry. Age. Gazette of Aug. 13, 1913.

TYPICAL STEAM LOCOMOTIVES

Item	Atlantic (4–4–2)	Pacific (4–6–2)	Consolidation (2–8–0)	Mikado (2–8–2)

Tractive effort per lb. of mean effective pressure, lb	157.30	219.7	305.3	300

(a) Mean effective pressure taken as 0.8 of boiler pressure. Piston valve and Walschaert valve gear used on all four locomotives.

OPERATION OF STEAM LOCOMOTIVES. — Below are given some of the more important facts in regard to steam locomotive operation.

Location of Coal and Water Stations. — Coal and water stations for replenishing the tender are required at intervals, depending upon the topography of the line and volume of traffic. On fairly level roads coaling stations are required at intervals of 50 or 60 miles for freight engines and 120 miles for passenger engines. Water stations are needed at about 50-mile intervals for passenger and 25-mile intervals for freight service. These distances may be much reduced on heavy grades. The location of water stations is also a matter of available water supply. Where possible water should be taken at regular stops.

Fuel and Water Consumption. — This is very variable depending upon topography and alignment of road, kind of service, frequency of stops, whether single or double track, climatic conditions, weight of trains, etc. The number of pounds of coal burned per locomotive mile averages about 104 for passenger, 208 for freight, 130 for mixed, 108 for switching and 150 for all types of service. The actual water evaporated varies from 4.5 to 6.5 lb. per pound of coal burned. The first figure is for a coal consumption of 200 lb. and the last for 65 lb. per sq. ft. of grate per hour.

In some parts of the U.S. oil is used for fuel on account of the high cost of coal. It results in a greater expense for upkeep of boilers on account of intense heat, but in the far west and southwest is economical on the whole.

Use of Different Kinds of Coal. — Exhaust nozzles and draft appliances can be arranged to suit any one of various kinds of coal, and arrangements should be made to use only the kind of coal for which the engine is "drafted" as other kinds are burned at a less efficiency and consequently at what is probably a larger expense even though the cost per ton of the improper coal is less.

Idle Steaming. — Whenever a locomotive is standing idle under steam, coal is being consumed. This idle time should be reduced to a minimum by avoiding firing up a long while before an engine is needed, and by keeping trains moving while they are on the road. Roads having traffic largely of one kind can show better results in this particular than those having a mixed traffic composed of equal parts of all kinds.

Lubrication. — The friction in a locomotive is large, ranging from about 20 per cent of the total power of the engine to a maximum of 50 per cent or more under certain conditions of passenger service. Probably 35 per cent is a fair average. In many cases an appreciable economy can be instituted by increasing the quantity of oil allowed for an engine. Most motive power officials are strangely blind in this respect. Generally oil consumption is kept at a minimum, and enough coal is burned to overcome the resulting friction. The proper method is to so arrange the ratio of oil to coal that the total expense for the two is a minimum.

Blowing-off. — Boilers must be blown off and washed out at intervals depending upon the quality of water used.

COSTS.—The first cost of a steam locomotive is from 6 to 7 cents per pound of weight, including tender.

Annual Costs. — The cost of maintenance and repairs ranges from $2000 to $3500 per locomotive per year, an average figure being $2600.

The average life of a locomotive is about 20 years; hence in addition to the cost of maintenance and repairs an annual depreciation of 5 per cent of the first cost should be charged against the locomotive. In addition, an interest charge of, say, 5 per cent of the first cost should be included.

The operating costs are as follows, the figures being for ordinary mixed service on a trunk line with moderate grades:

Wages of crew,	10.6 cents per loco.-mile
Coal, at $3.00 per ton,	18.9 cents per loco.-mile
Oil, waste, etc.,	0.3 cent per loco.-mile
Wipers,	0.5 cent per loco.-mile
Repairs,	11.3 cents per loco.-mile
Total operating cost,	41.6 cents per loco.-mile

The average cost of operation of a locomotive, including wages of conductor and flagman, is about $50 per day, on the basis of 100 miles being a day's work.

The total annual cost of a locomotive costing initially $20,000 and covering an average of 100 miles per day would then be roughly:

Operation	$10,000
Maintenance and repairs	2,600
Depreciation	1,000
Interest	1,000
Total	$14,600

Y., 1907; Interstate Commerce Commission, *Statistics of Railways in the United States, 1910*, Washington; Pettigrew, W. F., *A Manual of Locomotive Engineering*, London, 1909; numerous articles in *Railway and Locomotive Engineering;* and the *Railway Age Gazette*.

[L. E. Moore.]

LOGARITHMS. — The logarithm of a number A, to a given base b, is the power n to which that base b must be raised in order to equal the number A. Thus, if $b^n = A$, then n is the logarithm of A to the base b, which may be written $n = \log_b A$. From this definition the following properties are readily deduced, where A and B are any two numbers.

$$\log AB = \log A + \log B.$$

$$\log \frac{A}{B} = \log A - \log B.$$

$$\log A^n = n \log A.$$

Characteristic and Mantissa. — These three equations hold irrespective of what is chosen as the base of the logarithms, provided the same base is used for each logarithm. In the common or Brigg's system of logarithms the number 10 is chosen as the base. In such a system the logarithm of any number may be expressed directly in terms of the logarithm of a number (including decimal fractions as numbers) between 1 and 10. For example:

$$\begin{aligned} \log_{10} 376.42 &= \log (100 \times 3.7642) \\ &= \log 100 + \log 3.7642 \\ &= 2 + \log 3.7642, \end{aligned}$$

since the power to which 10 must be raised to give 100 is 2. Similarly, $\log_{10} 3764.2 = 3 + \log 3.7642$. The logarithms of all numbers between 1 and 10 are less than unity. The whole number or integer part of a logarithm is called its "characteristic" and the fractional part its "mantissa." The characteristic of the logarithm of a number less than unity is negative. For example:

$$\begin{aligned} \log 0.037642 &= \log (\tfrac{1}{100} \times 3.7642) \\ &= \log 1 - \log 100 + \log 3.7642 \\ &= -2 + \log 3.7642. \end{aligned}$$

In general, *the characteristic of a number greater than unity is positive and is one less than the number of figures to the left of the decimal, while the characteristic of a number less than unity is negative and is one greater than the number of ciphers between the decimal and the first significant figure.* A table of logarithms gives the mantissas only, the characteristics being determined by the above rule. Such a table is given below.

Antilogarithms. — If $n = \log A$, then A is the number whose logarithm is n. This may be written symbolically

$$A = \log^{-1} n.$$

A is then called the antilogarithm or inverse logarithm of n. The antilogarithm of a number (i.e., the number which has the given number for its logarithm) is found from a table of logarithms by finding the number in the margin corresponding to the decimal point of the given number in the table, and fixing the decimal point by the rule given above. Example:

$$\log^{-1} 1.6464 = 44.3.$$

Use of Logarithms. — Logarithms are used in the processes of multiplication, division, raising to powers and taking roots. For example, to find the product of two numbers take from the table the logarithms of the two numbers,

add these logarithms, and then from the table find the number of which this is the logarithm. The position of the decimal point is fixed by the value of the mantissa in the sum of the two logarithms. By adding a whole number to a mantissa and subtracting the same number from the characteristic the mantissa of the final result can always be kept positive.

Examples. — Multiply 376.2 by 0.587:

$$\begin{aligned} \log 376.2 &= \quad 2 + .57541 \\ \log 0.587 &= -1 + .76863 \end{aligned}$$

$$\text{Adding gives } 1 + 1.34404 = 2.34404$$

therefore $376.2 \times 0.587 = 220.8.$

Divide 37.62 by 587:

$$\begin{aligned} \log 37.62 &= 1 + .57541 = \quad 1.57541 \\ \log 587 &= 2 + .76863 = 2 + .76863 \end{aligned}$$

$$\text{Subtracting gives} - 2 + .80678$$

therefore $$\frac{37.62}{587} = 0.06409.$$

NATURAL LOGARITHMS. — (*See also Roots and Powers.*) The base of the so-called natural system of logarithms is the value of the expression $\left(1 + \frac{1}{n}\right)^n$ when n is taken equal to infinity. The numerical value of this expression is found by expanding $\left(1 + \frac{1}{n}\right)^n$ by the binomial theorem (*see Series*), and is equal to $2.718282 +$. This number is usually represented by the symbol ϵ, that is,

$$\epsilon = 2.718282 +, \text{ or } 2.718 \text{ approximately.}$$

Logarithms to this base are readily calculated by means of Taylor's series (*see Series*); also this number ϵ enters in a very simple manner into various mathematical and physical relations (*see Equations, Differential; Transient Electric Phenomena; Hyperbolic Functions; Trigonometric Functions*).

The relation between a logarithm of any number A to any base b and the logarithm of A to any other base a is

$$\log_b A = \frac{\log_a A}{\log_a b}.$$

Hence $$\log_\epsilon A = 2.30259 \log_{10} A.$$

From this last relation the natural logarithm of any number may be found directly from the table of common logarithms.

Example. —

$$\log_\epsilon 376.2 = 2.3026 \times 2.57541 = 5.930.$$

The natural logarithm may also be taken directly from the table of exponential functions (q.v.), remembering that $\log_\epsilon A$ is the number in the margin of the table corresponding to the number equal to A in the columns of the table.

The symbol "ln" is frequently used for the natural logarithm and the symbol "log" without a subscript is usually employed as an abbreviation for the logarithm to the base 10.

[W. A. DEL MAR.]

LUBRICANTS AND LUBRICATION. — (*See also Bearings; Friction.*)

Ordinary lubricants may be classified as follows:

Vegetable Oils. — Commonly employed vegetable oils are linseed, cottonseed, rape and castor. Vegetable oils decompose at comparatively low temperatures. They are used chiefly for compounding with mineral oils.

Animal Fats. — Animal fats ordinarily employed for lubrication are tallow, neat's-foot, lard, sperm, wool grease and fish oil. Like vegetable oils they decompose at comparatively low temperatures and are used chiefly for compounding with mineral oils.

Mineral Oils. — These are all petroleum products, and form the whole or the greater part of most of the lubricants employed.

Solid Lubricants. — Dry graphite, soapstone and mica are sometimes used as lubricants for slow-speed work when the bearing surface is restricted in area and the load to be carried is very large.

"Deflocculated" Graphite. — In 1906 E. G. Acheson discovered a process of producing a fine, pure, unctuous graphite, which when heated with a solution of tannin would remain suspended in water for months. The graphite thus suspended in water, known as "aquedag" has been successfully used as a lubricant (*Trans. A.I.E.E., 1907*). Acheson's "deflocculated" graphite, as the graphite in the finely divided form is called, has also been suspended in oil, the oil emulsion being known as "oildag," making an excellent lubricant.

Greases. — Compounds of oils and fats containing sufficient soap to form a more or less solid mass at ordinary temperatures are called greases. Lime soda or lead soaps are used in these compounds. For very high pressures graphite, soapstone and mica are sometimes added to the grease.

QUALIFICATIONS OF A GOOD LUBRICANT. — The generally accepted conditions of a good lubricant are as follows:

1. "Body" (i.e., viscosity) enough to prevent the surfaces to which it is applied from coming in contact with each other.
2. Freedom from corrosive acid, of either mineral or animal origin.
3. As fluid as possible consistent with sufficient "body."
4. Low coefficient of friction (as determined in a standard bearing).
5. High "flash" and burning points.
6. Freedom from all materials liable to produce oxidation or "gumming."

The examinations to be made to verify the above are both chemical and mechanical, and are usually arranged in the following order:

1. Identification of the oil, whether a simple mineral oil, or animal oil, or a mixture. 2. Density. 3. Viscosity. 4. Flash point. 5. Burning point. 6. Acidity. 7. Coefficient of friction. 8. Cold test.

Test for Fats. — Heat a small quantity of the oil in a small test tube 15 minutes with small pieces of metallic sodium or caustic potash. If fatty oil is present, a soapy mass will form at the top. (*Gebhardt.*)

Test for Tarry Matter. — Dissolve a small quantity of the oil in from 10 to 20 times its bulk of gasoline; tar and other insoluble matter will be precipitated. (*Gebhardt.*)

Specific Gravity. — This is usually made with a hydrometer, graduated according to the Baumé scale. At 60° F.

$$\text{Specific gravity} = \frac{140}{130 + \text{degrees Baumé}}.$$

Viscosity. — Viscosity, or internal friction, is usually determined by observing the time required for a given amount of oil to flow through a standard orifice. By "specific viscosity" is meant the ratio of the time for the oil to run out to that required for an equal volume of water at 60° F. The temperature of the oil should always be observed and stated. Engine oils are usually tested for viscosity at 70° F. and cylinder oils at 212° F. (*Gebhardt.*)

Flash Point. — The flash point is determined by heating a sample of oil in a cup at the rate of 15° F. per minute until a spark will ignite the vapor; the corresponding temperature is the flash point. The flash point as thus determined depends to some extent upon the surface exposed, the size of the spark, the distance between spark and surface of oil and the dimensions of the cup. (*Gebhardt.*)

Burning Point or Fire Test. — By continuing the application of heat and noting the temperature at which the oil itself takes fire and continues to burn, the burning point is determined.

Acidity. — The presence of free acid is determined by shaking up equal quantities of oil and water and testing with litmus paper.

Cold Test. — The cold test is the temperature at which the oil will just flow.

Friction Test. — The coefficient of friction as determined from friction-testing machines gives but little information concerning the action of the oil under the widely different conditions found in practice. (*Gebhardt.*)

Properties of Vegetable and Animal Oils. — The following data are taken from Gebhardt's *Steam Power Plant Engineering.*

Kind of oil	Specific gravity		Flash test, ° F.
	Water as 1.00	Baumé	
Lard	0.9175	23	505
Sperm	0.8815	29	478
Tallow	0.9080	24.5	540
Cottonseed	0.9210	22	518
Linseed	0.9299	19	505
Castor	0.9639	15	...
Palm	0.9046	25	405
Rape-seed	0.9155	23	...

Properties of mineral oils as compounded for ordinary use are given below.

Grease Lubricants. — Tests made on an Olsen lubricant testing machine at Cornell University are reported in *Power*, Nov. 9, 1909. It was found that some of the commercial greases stood much higher pressures than the oils tested, and that the coefficients of friction at moderate loads were often as low as those of the oils. The journal of the testing machine was 3¾ inches diameter, 3⅓ inches long, and the babbitt bearing shoe had a projected area of 5.8 square inches. The speed was 240 revolutions per minute and each test lasted one hour, except when the bearing showed overheating. The following are the coefficients of friction obtained in the tests:

RELATIVE VALUES OF FRICTION COEFFICIENT WITH GREASES AND OILS

Lb. per sq. in.	Mineral grease	Animal grease	Graphite grease	Mineral grease	Engine oil	Engine oil	Grease	Grease

431.0	0.050	0.035	....	0.028	....	....	0.026	0.019

APPLICATIONS OF VARIOUS TYPES OF LUBRICANTS. — The type of lubricant to use in any case depends upon:

1. The cost due to consumption of lubricant.
2. The saving in annual cost due to lessening of wear of bearings, guides and other rubbing surfaces.
3. The cost of the energy saved (as the result of decreased friction losses) due to the use of the lubricant.

For minimum annual cost the sum of the last two items should equal the first. Estimates of this kind are difficult to make, and the result is that the kind of lubricant used in any specific case is usually determined by experience.

The following table, from a paper in *Power*, December, 1905, p. 750, gives the kind of lubricant ordinarily employed for various purposes, together with their approximate characteristics. The cold test of all these oils, except oil for refrigerating machinery, is given as 30° F. Refrigerating-machinery oil should not solidify above 0° F.

METHODS OF LUBRICATION. — The commonest type of "lubricator" on engines or dynamos is the simple oil cup with sides of glass, so that the level of the oil in the cup can be seen. Any type of lubricator in which the flow of oil can be seen is known as a "sight feed." The flow of oil is regulated by a needle valve in the base of the cup.

Lubrication of Crossheads, Crank Pins, etc. — In applying oil to rubbing surfaces, both of which are in motion, various devices are used by means of which the oil cup can be kept at rest. A stationary oil cup may be used with a "wiper" on the moving member, or a "telescopic," "pendulum" or "centrifugal" oiler may be employed. Sometimes the crank, connecting rod and crossheads are inclosed in a casing the bottom of which is filled with oil so that at each revolution the end of the connecting rod splashes oil over all the parts.

Oil Rings and Chains. — The bearings of small high-speed engines and dynamos are frequently provided with rings or chains running loosely over the journal and dipping into an oil bath in the pedestal below the bearing. The rotation of the journal gives enough motion to the rings to enable them to carry up sufficient oil from the bath to keep the bearing surfaces bathed in oil.

Cylinder Lubrication. — The oil must be forced into steam cylinders against the steam pressure. This is usually accomplished by means of specially constructed cylinder cups, hydrostatic lubricators or force pumps. A brief description of the more common forms of these devices will be found in Gebhardt's *Steam Power Plant Engineering*.

APPLICATIONS AND CHARACTERISTICS OF VARIOUS OILS

Kind of oil and application	Specific gravity, Baumé	Flash test, °F.	Fire test, °F.	Viscosity at 70° F. (Water = 1)
High-pressure cylinder oils: For cylinders using dry steam at from 110 to 210 lb.	25–24.5	600–610	645–660	175–205
General cylinder oil: For cylinders using dry steam at from 75 to 100 lb. Also for air compressor cylinders when the oil is made from steam-refined mineral stock and has a viscosity of 200.	26–25.5	550–585	600–630	180–190
*Wet cylinder oil** For cylinders using moist steam, especially in compound- and triple-expansion engines.	25.8–25.3	560–585	600–630	150–185
Gas-engine cylinder oil†	26.5	320	350	300
Automobile gas-engine oil‡	29.5	430	485	195
Heavy engine and machinery oils: For heavy slides and bearings, shafting and horizontal surfaces.	30.5–29.5	400	440–450	170–195
General engine and machinery oils: For high-speed dynamos and other comparatively heavy machines.	30.8–30	400–420	450–470	175–190
Fine and light machine oils: For fine work, such as printing presses, sewing machines, typewriters, spindles, etc.	32.5–30.2	400	440	110–160
Cutting oils: For cutting tools, screws, etc.	27–23	410–420	475–480	210–175
Refrigerating machine oils	30.2	200	225	165
Wet service and marine oils§	28	430	475	230
Greases: Various kinds, used in special work requiring high pressures and low velocities.	......	....	....	.....

* May contain not over 2 to 6 per cent of refined acidless tallow oil in the high-pressure oils and not over 6 to 12 per cent in the low-pressure oils.

† Neutral mineral oil compounded with soap. The soap will not decompose at high heat, and although not a lubricant serves as a vehicle for carrying some oil.

‡ Owing to lack of body this oil will not deposit carbon on the sparking points.

§ May contain 30 to 40 per cent of pure strained lard oil.

Oil-feed Systems. — In power plants oil is supplied continuously to the bearing surfaces of the various engines and generators by means of an oil-feed system, comprising essentially a supply tank, pump and the necessary piping. Oil filters and purifiers are also used in connection with the oiling system, to eliminate the impurities which collect in it due to dust, wear of bearings, exposure to the heat and to the atmosphere. See article on *Power Stations*.

AMOUNT OF OIL REQUIRED FOR ENGINES. — J. H. Spoor, in *Power*, Jan. 4, 1910, has made a study of a great number of records of the amount of oil used for lubricating cylinders of different engines, and has reduced them to a systematic basis, i.e., the number of pints of oil used in a 10-hour day for different areas of surface lubricated. The surface is determined in square inches by multiplying the circumference of the cylinder by the length of stroke. The results are plotted in a series of curves for different types of engines, and approximate average figures taken from these curves are given below:

PINTS OF CYLINDER OIL IN 10 HOURS

Type of Engine	Square inches lubricated								
	1000	2000	3000	4000	6000	8000	10,000	12,000	18,000
Automatic high speed	2	....	....	....	....	....	....	....	....
Simple slide valve..	0.5	....	....	....	....	....	....	....	....
Compound..........	....	2	....	3.5	4.3	5	5.5	6	6.5
Corliss:									
Average...........	0.9	1.65	2.25	3.75	....	....	....	....	....
Maximum.........	1.2	2.25	....	....	....	....	....	....	....
Minimum.........	....	1.00	....	....	....	....	....	....	....

As shown in the figures under 2000, Corliss, a certain engine may take 2¼ times as much oil as another engine of the same size. The difference may be due to smoothness of cylinder surface, kind and pressure of piston rings, quality of oil, method of introducing the lubricant, etc. Variations in speed of a given type of engine and in steam pressure do not appear to make much difference, but the small automatic high-speed engine takes more oil than any other type. Vertical marine engines are commonly run without any cylinder oil, except that used occasionally to swab the piston rods.

The amount of engine oil required will of course depend upon the number of cups on the engine and the size of the various bearings. For a 1000-h.p. Corliss engine the Vacuum Oil Company state that the amount of engine oil would not exceed twice the amount of cylinder oil required.

MACHINE TOOLS, ELECTRICAL OPERATION OF. — (*See also Motors, Industrial Applications of.*) When the work of equipping a machine tool with motor drive is undertaken, there are certain features which should be taken into account and properly analyzed, as the conditions of operation generally vary greatly with the product manufactured. If a tool is intended for a certain specialized kind of work, information on the following points should be given:

1. The exact class of work which the tool is to accomplish.
2. If the power required to remove the metal is not known, then a statement should be made as to the approximate feed and cutting speeds to be taken.
3. Careful analysis should be made of the time required to load and unload the machine, to determine the feasibility of employing auxiliary means other than manual labor for loading the tools.

From this information an approximate determination can be made as to the intermittency of operation of the tool, in order to decide whether an intermittently rated motor or a continuously rated motor will be required. From a knowledge of the physical shape of the work, a determination can be made as to whether an adjustable-speed motor will result in economy of time, if used on this particular class of tool. The tool builder can then decide upon the proper type of controller, and its most desirable location from an operating point of view for the workman.

If a special type of tool is not desired and it is preferable to purchase one with such characteristics that it can be used for general manufacturing, one should determine as nearly as possible the range of material or work for which it will be used in straight manufacturing operations. A knowledge of this will undoubtedly permit of a better motor and tool selection than the simple purchase of a standard stock tool.

TYPE OF MOTOR. — The following table will aid in the choice of the proper motor for machine tool application.

It must be kept in mind that various circumstances, such as size or roughness of work, flywheel capacity, etc., may call for radical departures in choice of motors, this list being compiled to meet average conditions.

Shunt Motors are used in the following cases: when the work is of a fairly steady nature; when considerable range of adjustment of speed is required, as on lathes and boring mills, and on group and line-shaft drives, etc.

Compound-wound Motors are used where there are sudden calls for excessive power of short duration, as on planers, punch presses, etc.

Series Motors should be used where speed regulation is not essential and where excessive starting torque and slow starting speeds are required, as, for instance, in moving carriages of large lathes, in raising and lowering the cross rails of planers and boring mills, and for operating cranes.

When in doubt as to the choice of compound or series motors of small horsepower, the choice might be determined by the simplicity of control in favor of the series motor. Series motors, however, should never be used when the motor can run without load, as the speed would accelerate beyond the point of safety.

Induction Motor. — The alternating-current motor of the squirrel-cage rotor type corresponds to the constant-speed, shunt, direct-current motor, but with a high-resistance rotor it approaches more closely the characteristics of a compound direct-current motor. It is understood that the variable-speed machines, checked in this list under the alternating-current squirrel-cage rotor column, have the necessary mechanical speed changes.

The slip-ring induction motor with external rotor resistance would be used

× Squirrel-cage rotor.
Squirrel-cage rotor — high starting torque.
⊕ Slip-ring induction motor with external rotor resistance.
✠ Might be used for tire lathes as it allows slowing down when cutting hard spots.

for variable speed, but this must not be construed to mean that it corresponds to a direct-current, adjustable-speed motor, as it has the characteristics of a direct-current shunt motor with armature control.

The self-contained, rotor-resistance type would be used for line-shaft drives, and for groups when of sufficient size.

Multi-speed Alternating-current Motors are those giving a number of definite speeds, usually 600 and 1200 or 600, 900, 1200 and 1800 r.p.m., and are made for both constant horse-power and constant torque. These motors would be used where alternating current only was available, or direct current limited; and the speed range of the motor, together with one or two change gears, would give the required speeds.

Shaft Couplings. — In connection with the selection of motors, standard shafts and shaft extensions should be chosen so that spare parts and interchanges may be made with the least cost and time. A number of standard shafts and shaft extensions are shown in the sketches in Fig. 1.

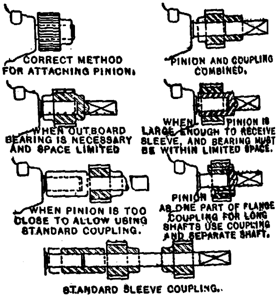

Fig. 1. Standard Shaft Couplings

CONTROL EQUIPMENT. — The choice of control, whether it be for old or new tools, in the majority of cases is fully as important as that of the motor. In selecting the control it is necessary to consider the nature of the work, the accessibility of the controller to the operator, the method of attaching it to the tool and in some cases its relative position to other tools; for instance, an open-type starting rheostat should not be exposed to danger of short-circuit from flying chips.

When installing controllers, accessibility in case of accident should be kept in mind, even though of little importance as far as starting up is concerned. The starting apparatus should be placed where the motor or some of the moving parts can be seen by the operator. On individual motor-driven tools, where the motor is started and stopped many times a day or where the starting conditions are of a severe nature, or where tools are edged along, drum-type controllers with extra heavy starting resistance should be used. For adjustable speed motors, using the drum-type control, the field control should be through fingers making contact on segments of the controller drum and not by sliding contacts on a dial. Motors above 40 or 50 horse-power under these severe conditions are best operated by a master controller which operates contactors for cutting out steps of starting resistance, and if adjustable speed, the field control should be taken care of by fingers making contact on segments of the drum. This class of starting apparatus will stand any quantity of abuse and, by the addition of a simple current limit relay device, becomes practically a fool-proof protection for the motor. There are cases where it might be advantageous to use master controllers and contactors even with smaller motors. The controlling apparatus as well as the motor in the case of individual drives should be attached directly to the tool when possible. This arrangement allows moving the tool by simply disconnecting the leads and connecting them in the new position. In case of portable tools this, of course, is an absolute necessity.

Upon the convenient arrangement of the control depends, to a considerable degree, the output of the tool. The importance of the arrangement from the standpoint of the operator cannot be ignored, since the output of a tool will be materially increased when an operator can start and stop the tool and obtain

at all times maximum cutting speeds by simply turning a handle. The controller must be placed in a safe position and should be accessible for repairs, which very often means that some arrangement is necessary to bring the operating handle within easy access of the operator.

The convenience of control, which bears directly on production, is ignored in the majority of tools where the control is of the greatest importance. A familiar illustration of the convenience of control is the arrangement so commonly seen on lathes, whereby the operating handle travels with the tool carriage and allows the operator at all times a complete control of his tool.

Application of Reversing Motors. — One of the most interesting motor applications of recent date is the use of reversing motors for machine tools. The large increase in production due to this form of drive on planers is now generally appreciated, but the application of the reversing-motor drive in its various forms (which is almost unlimited) is not so well appreciated. It is applicable not only to planers, new and old, but to screw-, worm- and rack-driven slotters, keyseaters, turret lathes, wire- and tube-drawing machinery and to boring mills, when machining projections which are short in comparison with the total travel of the mill or when machining surfaces where projections prevent a complete revolution. Reversing motors are also applicable to that class of reversing machinery which is now reversed through clutches, shifting belts, etc., the cost of maintenance of which is usually high and the efficiency low.

The motors recommended for this service are of the commutating pole type with a speed range usually of from 250 to 1000 r.p.m. in sizes up to and including 100 horse-power planer rating; also a speed range of from 350 to 1200 r.p.m. in sizes up to 35 horse-power planer rating. Other speeds can be obtained when required. These combinations of speeds allow the motor in the majority of cases to be coupled direct to the driving shaft of the machine.

Starting, stopping and reversing are accomplished with sparkless commutation. In order not to brake (dynamically) from high speed in one violent step, means have been provided in the control to accomplish this in three distinct steps, braking down slowly from the high speeds and then quickening the brake action at the lower speeds by cutting out the brake resistance in two steps, thus completing the entire brake action without undue shock, in the shortest possible time. This feature, in addition to the quickness of the brake, will be recognized as a decided advantage in the maintenance of the machine. Incidentally, reversing is accomplished without the delay incident to the use of sluggish relays. After a failure of voltage with the master controller in the running position and upon closing the line circuit breaker, the motor will start up in the regular way, without additional complications in the control. This latter feature is advantageous in the event of the operator failing to return the master switch to the off-position. Cutting and return speeds are entirely independent of each other, so that it is possible to use the slowest cutting speed and the highest return speed, or vice versa, in any combination not exceeding four to one, with thirty-five to seventy cutting speeds and the same number of return speeds, depending on the size of the equipment. Special cases, where overlapping speeds are required or where the entire range of motor speeds is to be used in both directions for cutting, as in plate planers, can be readily provided for when the operating conditions are known.

Example. — In Fig. 2 curves *A*, *B* and *C* are for motor No. 2 and show the ampere input of a 10 horse-power, 1250 r.p.m. motor driving a 36-inch modern type planer through shifting belts. *A* is the return stroke of the planer table at a speed of 68 feet per minute; *C*, the cutting stroke, without cut, at 33.3 feet per minute; *B*, the same cycle but with a cut slightly less than 10 horse-power. The lost time on the cutting stroke, due to the belt slipping, is plainly seen, the

cutting speed falling off from 33.3 feet to 29.4 feet or 13 per cent. Curves *E*, *F* and *G* are made on the same machine when driven by motor No. 1, a 10-horse-

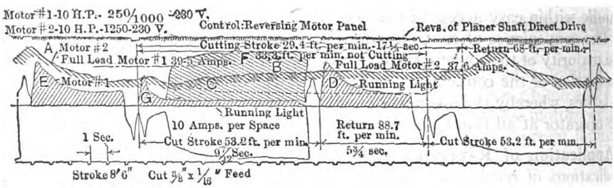

Fig. 2. Tests on 36 in. by 10 ft. Reversible Planer

power, 250 to 1000 r.p.m. reversing motor, direct connected. These curves are superimposed on the above curves for comparative purposes. No attempt was made in this set of curves to duplicate the slow cutting or return speeds of the belt-driven machines as the comparison would have shown power differences only. *E* is the return stroke of the planer table at a speed of 88.7 feet per minute; *G*, the cutting stroke at 53.2 feet per minute; *F*, the same cycle but with a cut of approximately 13 horse-power. The speed drop in this case is motor slow-down only. For comparison the speed of motor No. 1, curve *F*, was chosen as the most economical speed under the conditions which the test was made. The loss in time of the belt drive as compared with the direct-connected reversing-motor drive (the depth of cut and feed being the same in both cases) is 62 per cent.

MAGNETIC PROPERTIES OF IRON AND OTHER METALS.

—(*See also Electricity and Magnetism, Principles of; Magnetic Testing.*) For the definitions of magnetizing force and flux density see *Electricity and Magnetism, Principles of;* for the relations of the various units in which these quantities are expressed see *Units and Conversion Factors.*

Hysteresis Loop — Residual Magnetism and Coercive Force. — When a magnetic substance which is not magnetized initially is placed in a magnetic field the intensity of which is increased from O to H_m, the flux density produced

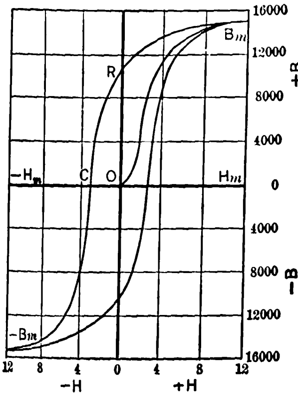

Fig. 1.

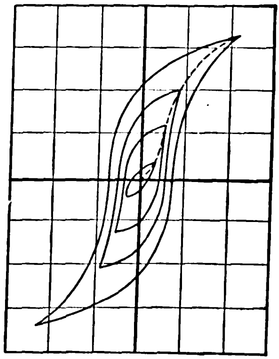

Fig. 2.

in the magnetic substance increases in the manner shown by the curve OB_m in Fig. 1. If the magnetizing force is then decreased to a value H the flux density does not return to the value corresponding to this value of H on the ascending curve, but decreases less rapidly than it increased. This phenomenon is known as "magnetic hysteresis."

When the magnetizing force is reduced to zero the flux density in general has a considerable value (OR in Fig. 1); this value of B is called the "remanent" or "residual" magnetism. To reduce the flux density to zero the magnetizing force must be reversed and increased in the reversed direction to a value OC, called the "coercive force." As the magnetizing force is still further increased in the reversed direction to a value numerically equal to the positive maximum, and then decreased to zero, reversed, and increased again to H_m, the flux density passes through the cycle of values represented by the closed loop. This closed loop is called the "hysteresis loop."

If the iron (or other magnetic substance) is not originally unmagnetized, this hysteresis loop will be shifted above or below the axis of H, but after a number of reversals of the magnetizing force between given positive and negative values, the loop will become practically symmetrical with this axis, particularly if the iron is continually jarred. In the armatures of electrical machines and the cores of transformers, in which the field intensity reverses a large number of times every second, and the iron is continually jarred, the relation between flux density and field intensity after a short interval of time is represented by a symmetrical loop of the form shown in Fig. 1.

The area inclosed by the hysteresis loop depends upon the maximum value of the flux density reached during the cycle, but the general shape remains

about the same. Fig. 2 shows a series of loops corresponding to various values of the maximum flux density. The area of the loop is also different for various kinds of iron or steel. $\frac{1}{4\pi}$ times the area of this loop when B and H are plotted to scale is equal to the ergs of heat developed in the iron per cubic centimeter per cycle. (*See section on Hysteresis Loss, below.*)

Permanent Magnets — Retentiveness. — An examination of this hysteresis loop also makes clear how a bar of steel may be permanently magnetized by placing it in a magnetic field. For, when the bar is removed from the field it retains a flux density approximately equal to the residual magnetism OR. In the case of a cast-iron or steel bar, properly hardened, the bar thus magnetized may be handled with comparative roughness without reducing to any considerable extent the strength of its poles, but in the case of a soft-iron bar even the slightest jar will cause it to lose its magnetism almost entirely. The property possessed by a magnetic substance of retaining its magnetization is called its "retentiveness."

Magnetic Saturation. — The difference between the flux density and magnetizing force, at any point in a magnetized substance, divided by 4π is defined* as the intensity of magnetization J at this point, viz.,

$$J = \frac{B - H}{4\pi},$$

or

$$B = H + 4\pi J.$$

The intensity of magnetization J is proportional to the *excess* of magnetic flux caused by the presence of the magnetic substance. As the magnetizing force in a magnetic substance is increased the flux density B at first increases much more rapidly, for soft iron a thousand or more times, than the magnetizing force H (i.e., the intensity of magnetization established is many times greater than the magnetizing force). However, for larger values of H the intensity of magnetization ultimately becomes constant and any further increase in B cannot be greater than the increase in H. When the intensity of magnetization has reached its saturation value the magnetic substance is said to be "saturated."

Wrought iron, cast iron, cast steel and sheet steel all become practically saturated at magnetizing forces below 100 ampere-turns per inch (50 gilberts per centimeter), but absolute saturation does not occur until the magnetizing force reaches about 5000 gilberts per centimeter, and in the case of some magnetic alloys even higher fields are required for absolute saturation. Hadfield and Hopkinson (*Jour. Elec. Eng., 1911, Vol. 46, p. 237*) give the following, as the results of an extended investigation.

1. The saturation value of J in absolute units for pure iron of density 7.80 is 1680 within 1 per cent. This is slightly lower than the values obtained by Ewing and Low and other experimenters.

2. In an annealed iron-carbon steel in which other elements are present in small proportions the saturation value of J is less than that of pure iron by a percentage equal to 6 times the percentage of carbon.

3. Quenching an iron-carbon alloy from a high temperature reduces the saturation value of J by a large but somewhat uncertain amount.

4. The addition of silicon or aluminium to iron results in a reduction in the saturation value of J which is roughly in proportion to the amount added, as

* The factor 4π arises from the original conception of intensity of magnetization as the magnetic moment per unit volume.

though the addition behaved as an inert diluent. If carbon be present, however, silicon seems to neutralize its action to some extent.

Permeability and Normal B–H Curves. — The magnetic permeability μ of a substance corresponding to any degree of magnetization is usually defined as the quotient of the flux density B by the magnetizing force H, that is

$$\mu = \frac{B}{H}.$$

On account of the hysteresis effect, however, this quotient may have any value within wide limits depending upon how the magnetization is produced. Consequently a more restricted definition of permeability is required in the case of highly magnetic substances like iron and steel. In such cases it is customary to take as the *normal* permeability of the substance corresponding to any given value of the magnetizing force, the quotient

$$\mu = \frac{B_m}{H_m},$$

where B_m is the flux density corresponding to the end of the symmetrical hysteresis loop produced by reversing the magnetizing force a number of times between the values $+H_m$ and $-H_m$. That is, the locus of the ends of the various symmetrical hysteresis loops (the dotted line in Fig. 2) is taken as the *normal* B–H curve of the substance, and the corresponding quotients B/H for any point on this curve is taken as the *normal* permeability corresponding to the value of B and H at this point.

The relation between permeability and magnetizing force or flux density is a complex one. As the flux density increases, μ reaches a maximum at a relatively low flux density (from 3000 to 8000 gausses) and then decreases ultimately to unity when the magnetizing force reaches a value so large that the intensity of magnetization J is negligible in comparison with H. This limiting condition, however, is never reached in practice.

Susceptibility. — The quotient of the intensity of magnetization J divided by the magnetizing force H is called the magnetic susceptibility κ corresponding to this magnetizing force; viz.,

$$\kappa = \frac{J}{H} \text{ whence } \qquad \mu = 1 + 4\pi\kappa.$$

FACTORS AFFECTING THE PERMEABILITY AND HYSTERESIS LOSS. — The normal permeability and the hysteresis loss (the latter is proportional to the area of the hysteresis loop) depend to a very great extent upon the physical structure and chemical constitution of the sample and the heat treatment to which it has been subjected. It has also been recently discovered (*Pender and Jones, Phys. Rev., 1913*) that when sheet steel is annealed in an alternating magnetic field, the permeability is increased in certain cases as much as 50 per cent, but there is no appreciable change in the hysteresis loss. The B–H curves of two samples taken from the same lot of material may even differ considerably. The permeability and hysteresis loss also depend to a slight extent upon whether the sheets are magnetized in the direction of rolling, or transverse thereto, being higher in the latter case.

Temperature and Aging. — Permeability and hysteresis also depend upon the temperature of the sample at the time the observations are taken, though the variation due to ordinary changes of temperature is slight. For very high temperatures, however, all magnetic substances become practically non-magnetic. This temperature corresponds to the major recalescence point, which is about 750° C. for steel of the quality used in armature and transformer

punchings. When steel is kept continuously at a moderately high temperature (100° C.), the hysteresis loop also gradually increases in size, and therefore the energy loss in the magnetic circuits of electric machines due to hysteresis increases with time. This effect is called "ageing." There is practically no ageing of silicon steel.

Chemical Composition of "Electrical" Sheet Steel. — Sheet-steel manufacturers make a special grade of sheet for electrical purposes, which they sell under various trade names. Such steel is always low in carbon content and, except silicon in the so-called silicon steels, all impurities are reduced to small amounts. Within the last decade the use of steel containing about 3 per cent silicon has come into extensive use, particularly for the magnetic circuit of transformers. The permeability of this steel is somewhat lower, in the useful range of flux densities, than that of ordinary electrical steel, but the area of the hysteresis loop, and therefore the hysteresis loss, is from 40 per cent to 60 per cent less; the specific resistance of silicon steel is also about 3 times greater than that of ordinary electrical steel, resulting in a reduction of about 70 per cent in the eddy-current loss (*see curves below*). Aluminium has much the same effect as silicon, but the aluminium alloy is not so easily rolled.

The following are typical chemical analyses of the two kinds of electrical steel, but it should be understood that considerable variations in the proportions of the various constituents occur in practice.

	Ordinary electrical steel *	Silicon steel
	Per cent	Per cent
Silicon	0.01	3.46
Phosphorus	0.08	0.04
Manganese	0.50	0.13
Sulphur	0.03	0.02
Carbon	0.06	0.06

* Parshall & Hobart, Electric Machine Design.

Of a large number of electrical steels analyzed by the Bureau of Standards (*Lloyd and Fisher, Trans. A.I.E.E., 1909, Vol. 28, p. 463*) none showed more than the slightest trace of vanadium.

Annealing of Sheet Steel. — Sheet steel as it comes from the rolling mill may be greatly improved in magnetic properties by proper annealing. The chief requirement seems to be that the steel be brought to a temperature about 100° C. above the major recalescence point, i.e., to a temperature of about 850° C., and then allowed to cool slowly down to a temperature of from 100 to 150° C., when it may then be removed from the annealing furnace and allowed to cool more rapidly. The time required for annealing is from 12 to 36 hours. The annealing is usually done after the punchings have been made, thus eliminating the hardening at the edges produced by the cutting; otherwise this hardening may produce a considerable increase in the hysteresis loss.

TYPICAL *B–H* AND PERMEABILITY CURVES. — In Fig. 3 are given the standard *B–H* curves used by one of the large manufacturing companies, and in Fig. 4 the permeability at various flux densities derived therefrom. It should be understood that these curves represent results obtainable under ordinary commercial conditions (joints not included) on iron and steel of

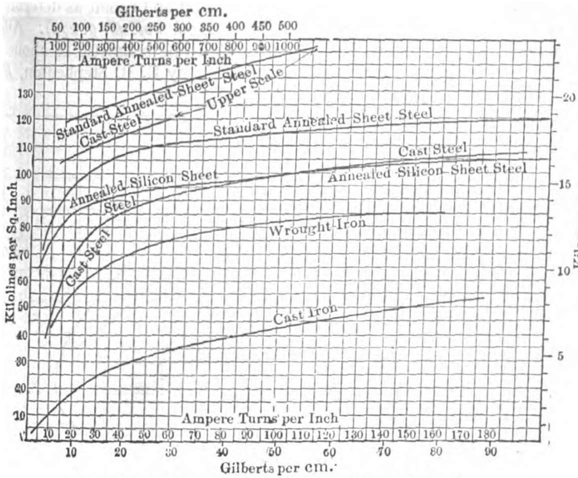

Fig. 3. Normal B-H Curves of Iron and Steel

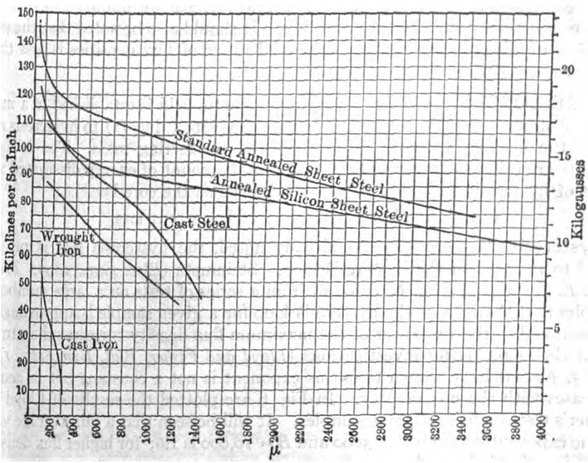

Fig. 4. Permeability Curves of Iron and Steel

the composition found suitable for electrical purposes. Ordinary commercial iron or steel will not, as a rule, have a permeability as high as given by these curves.

In Fig. 5 are given the permeability curves of nickel and cobalt as determined by Fleming, Ashton and Tomlinson (*Phil. Mag.*, *1899, Vol. 48, p. 271*). Alloys of certain non-magnetic metals have been found to be magnetic to about the same extent as nickel; see paper on *Heusler Alloys* by E. B. Stephenson, *Bull. 47* (*1911*), *University of Illinois, Eng. Exp. Stat.*

Maximum Permeability. — As indicated by the curves in Fig 4, the maximum permeability of sheet steel occurs below the range of commercial flux densities. A number of tests by the author showed that this maximum occurs at from 6 to 10 kilolines per square inch, the permeability decreasing rapidly with flux densities less than these values, the complete curve being similar in shape to the curves shown in Fig. 5. The author has obtained a maximum permeability of about 9000 c.g.s. units with ordinary electrical sheet steel, and a maximum of 13,000 c.g.s. units with silicon steel, carefully annealed in small lots in an alternating magnetic field (*Pender and Jones, Phys. Rev., 1913*). These exceptionally high permeabilities, however, are not obtained in practice under commercial conditions of annealing. It should also be noted that the permeability of silicon steel in the commercial range of flux densities is less than that of the ordinary low-carbon electrical steel.

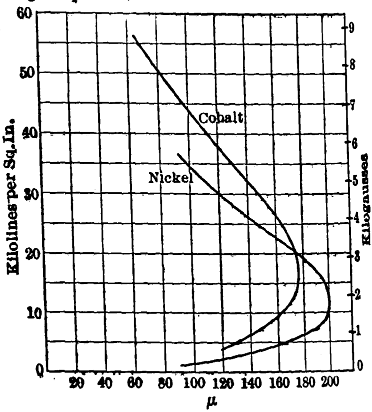

Fig. 5. Permeability Curves of Nickel and Cobalt

CORE-LOSSES. — When a varying magnetic field is established in a magnetic substance a certain amount of heat is developed due (1) to hysteresis and (2) to the electric currents induced in the conducting mass. The induced currents are called eddy currents, and the total amount of energy dissipated as a result of hysteresis and eddy currents is known as the core-loss, i.e.,

$$\text{Core-loss} = \text{hysteresis loss} + \text{eddy-current loss.}$$

Hysteresis Exponent. — As already noted, the hysteresis loss is proportional to the area of the hysteresis loop. Steinmetz (*Elec. Eng., 1890; Trans. A. I. E. E., 1892, Vol. 9, p. 3*) found from a series of tests on a large number of samples that the area of the hysteresis loop for a given sample is approximately proportional to the 1.6 power of the maximum flux density corresponding to the tip of the loop. Later investigations (*Lloyd and Fisher, Bull. Bur. Stds., 1909, Vol. 5, p. 453*) have shown that this exponent is not a constant but in general increases with the flux density. In Fig. 6 are plotted the results of Lloyd and Fisher's tests on five different samples. It will be seen that a fair average value of the exponent between $B = 3000$ and $B = 10{,}000$ is 1.6; for higher flux densities there is a decided trend upward.

Hysteresis Coefficient. — If the magnetic field throughout the iron is *uniform*, and the hysteresis exponent is assumed constant and equal to 1.6, then the power loss can be expressed by the formula

$$P_h = KVfB^{1.6}, \qquad \text{or} \qquad P_h = KWfB^{1.6},$$

where

V = volume of iron,
f = frequency of alternating field, in cycles per second,
B = maximum flux density,
W = weight or mass of the iron.

The value of the constant K depends upon the units in which the other quantities are expressed. If V is in cubic centimeters, B in gausses, f in cycles per second and P_h in ergs per second the formula is usually written

$$P_h = \eta V f B^{1.6}.$$

That is, the loss in ergs per cycle per cubic centimeter is $\eta B^{1.6}$. The constant η is known as Steinmetz's hysteresis coefficient and the quality of iron or steel with respect to hysteresis is frequently expressed in terms of this constant.

The hysteresis loss is also sometimes stated as the watts per pound at 10,000 gausses and 60 cycles. Let w_1 = hysteresis loss in watts per pound at 10,000 gausses and 60 cycles. Then the corresponding value of η is:

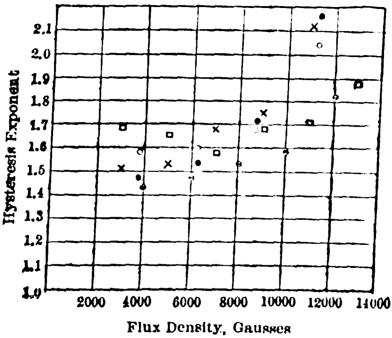

Fig. 6. Variation in Hysteresis Exponent

⊖ Ordinary electrical sheet, unannealed.
● Ordinary electrical sheet, annealed (German).
× 0.7 % silicon, annealed.
□ 3.4 % silicon, annealed.
○ Silicon-steel, annealed (German).

For Specific Gravity = d	Specific Gravity = 7.7	Specific Gravity = 7.5
$\eta = 0.000146\, w_1 d$	$\eta = 0.00113\, w_1$	$\eta = 0.00110\, w_1$

Note that w_1 is the hysteresis loss only, excluding the eddy-current loss, which is discussed below.

The following table gives the value of K in terms of η when the various quantities in the formula for hysteresis loss are in the units stated.

FORMULA FOR CALCULATING HYSTERESIS LOSS

$$P_h = KVfB^{1.6}$$

Power, P_h	Volume, V	Frequency, f	Flux density, B	K =
Ergs per sec.	Cu. cm.	Cycles per sec.	Gausses	η
Watts	Cu. cm.	Cycles per sec.	Kilogausses	$0.00631\,\eta$
Watts	Cu. in.	Cycles per sec.	Kilogausses	$0.1035\,\eta$
Watts	Cu. in.	Cycles per sec.	Kilolines per sq. in.	$0.00525\,\eta$

$$P_h = KWfB^{1.6}$$

Power, P_h	Weight, W	Frequency, f	Flux density, B	$K=$
Ergs per sec.	Grams	Cycles per sec.	Gausses	$\frac{\eta}{d}$
Watts	Kilograms	Cycles per sec.	Kilogausses	$6.31\frac{\eta}{d}$
Watts	Pounds	Cycles per sec.	Kilogausses	$2.86\frac{\eta}{d}$
Watts	Pounds	Cycles per sec.	Kilolines per sq. in.	$0.145\frac{\eta}{d}$

d = specific gravity = 7.7 for ordinary electrical sheets = 7.5 for silicon steel.

Hysteresis Loss for Various Substances. — The hysteresis loss in iron and steel and other magnetic metals depends to so great extent upon their chemical composition, physical structure, heat treatment, etc., that average values have no significance. The following table is intended to give the range in the value of the hysteresis coefficient for iron and steel used in electrical machinery; figures for nickel and cobalt are also included.

VALUES OF HYSTERESIS COEFFICIENT

η = ergs per cycle per cubic centimeter for $B = 1$ gauss

w_1=watts per pound at 60 cycles for $B = 10,000$ gausses

Metal	Values of η		Values of w_1	
	From	To	From	To
Silicon steel, annealed sheets	0.0006	0.0015	0.55	1.36
Ordinary electrical sheets, annealed	0.00095	0.004	0.84	3.5
Soft cast steel	0.003	0.012	2.7	11
Cast iron	0.011	0.016	10	14
Forged steel	0.015	0.025	13	22
Hard cast steel	......	0.028	....	25
Cobalt	0.012	......	11	....
Nickel	0.013	0.040	12	35

The extreme low values of η can seldom be uniformly realized in practice. One of the large manufacturing companies uses for design purposes the values $\eta = 0.00145$ for silicon steel and $\eta = 0.0033$ for ordinary electrical sheets, these values allowing a considerable margin for variations in the quality of the steel. For close design the particular quality of steel to be used should be carefully tested (*see Magnetic Testing*) and the test results used.

In Fig. 7 are plotted hysteresis loss curves for various values of η assuming the $B^{1.6}$ law.

Eddy-Current Loss. — When an alternating magnetic field is established in a conducting material alternating currents are set up in it due to the alter-

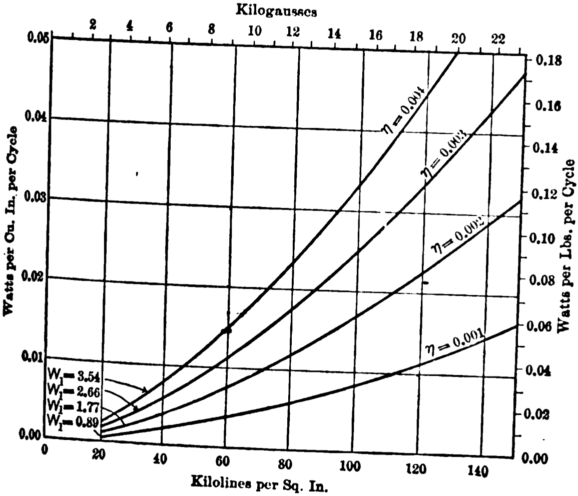

Fig. 7. Hysteresis Loss

nating e.m.f. produced by the alternating field. Consider a sheet of iron, Fig. 8, subjected to a *uniformly* distributed alternating field parallel to its faces. The dots indicate the flux lines perpendicular to the page and the loops the induced currents. Let

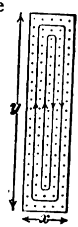

Fig. 8.

B = flux density, in gausses,
x = thickness of plate, in centimeters,
ρ = specific resistance of plate, in abohms per cm-cube,
$\dfrac{dB}{dt}$ = rate of change of flux density with time, gausses per second.

Then the *instantaneous* power loss per cubic centimeter of the sheet, when the thickness x is very small (1 per cent or less) compared with the width of the plate, is

$$p = \frac{x^2}{12\rho}\left(\frac{dB}{dt}\right)^2.$$

The *average* power loss per cubic centimeter for a complete cycle of variation of the flux, in ergs per second, is

$$P_e = \frac{x^2}{12\rho} \times \left(\text{root-mean-square value of } \frac{dB}{dt}\right)^2.$$

It should be noted that this average loss depends upon the form factor (*see Alternating Currents*) of the rate of change of flux density, the latter being proportional to the counter e.m.f. induced by the varying field of the magnetizing coil.

If the induced voltage and therefore the flux density varies according to a sine function of the time, i.e., if $B = B_m \sin(2\pi ft)$, where B_m is the maximum

value of the flux density, f the frequency, and t the time, then the average power loss due to eddy currents per cubic centimeter is

$$P_e = \frac{(\pi x f B_m)^2}{6\rho}.$$

If the voltage wave has a form-factor h, the loss for the *same* B_m is greater than this by the factor $\left(\frac{h}{1.11}\right)^2$; see below.

The corresponding formula for the eddy-current loss per unit volume in a wire or cylinder of radius r, magnetized *parallel* to its axis, to a *uniform* flux density over its cross section is

$$P_e = \frac{(\pi r f B_m)^2}{4\rho}.$$

Eddy-current Coefficient. — In practice the field in the sheets is seldom perfectly uniform, and eddy currents flow from one sheet to the other, unless they are insulated from each other; consequently the eddy-current loss in a core made up of a bunch of sheets is usually greater than that given by the above formula. The eddy-current loss in a laminated core is therefore usually expressed by the formula

$$P_e = K_1 V (xfB)^2,$$

or

$$P_e = K_1 W (xfB)^2,$$

where V and W are the volume and weight respectively of the core and B is the maximum flux density. The coefficient K_1 is determined from actual tests on a suitable sample (*see Magnetic Testing*).

The coefficient K_1 (aside from its dependence upon the units in which the various quantities are measured) depends upon the specific resistance of the iron, the wave shape of the induced voltage, the distribution of flux in the sheets, the degree to which the sheets are insulated from each other, and upon the shape of the magnetic circuit in so far as this affects the distribution of flux. The results of the tests by Lloyd and Fisher also indicate that K_1 depends upon the value of B, or, in other words, that the eddy-current loss does not vary directly as the square of the maximum flux density, all other conditions being the same. At high frequencies, above 100 cycles per second, the loss also increases less rapidly than the square of the frequency, due to the increase in the effective resistance of the sheets as the result of an action similar to the skin effect (q.v.) in a wire carrying a rapidly alternating current.

When the loss P_e is expressed in watts, V in cubic centimeters, f in cycles per second, x in centimeters and B in gausses, the coefficient K_1 may be represented by the symbol ϵ, and the formula for eddy-current loss becomes

$$P_e = \epsilon V (xfB)^2.$$

The eddy-current loss is frequently stated as the watts per pound at 10,000 gausses and 60 cycles for a thickness of sheet corresponding to No. 29 on the sheet-steel gage (= 0.0141 inch = 0.0358 centimeter). Let w_2 = eddy-current loss in watts per pound at 10,000 gausses and 60 cycles for sheets 0.0141 inch thick. Then the corresponding value of ϵ is:

Specific Gravity = d	Specific Gravity = 7.7	Specific Gravity = 7.5
$\epsilon = 0.0000478\, w_2 d$	$\epsilon = 0.000368\, w_2$	$\epsilon = 0.000359\, w_2$

FORMULA FOR CALCULATING EDDY-CURRENT LOSS *

$$P_e = K_1 V (xfB)^2$$

Power, P_e	Volume, V	Thickness of sheets, x	Frequency, f	Flux density, B	$K_1 =$
Ergs per sec.	Cu. cm.	Cm.	Cycles per sec.	Gausses	ϵ
Watts	Cu. cm.	Cm.	Cycles per sec.	Kilogausses	0.1ϵ
Watts	Cu. in.	In.	Cycles per sec.	Kilogausses	10.58ϵ
Watts	Cu. in.	In.	Cycles per sec.	Kilolines per sq. in.	0.254ϵ

$$P_e = K_1 W (xfB)^2$$

Power, P_e	Weight, W	Thickness of sheets, x	Frequency, f	Flux Density, B	$K_1 =$
Ergs per sec.	Grams	Cm.	Cycles per sec.	Gausses	$\frac{\epsilon}{d}$
Watts	Kilograms	Cm.	Cycles per sec.	Kilogausses	$100\frac{\epsilon}{d}$
Watts	Pounds	In.	Cycles per sec.	Kilogausses	$292\frac{\epsilon}{d}$
Watts	Pounds	In.	Cycles per sec.	Kilolines per sq. in.	$7.01\frac{\epsilon}{d}$

d = specific gravity = 7.7 for ordinary electrical sheets = 7.5 for silicon-steel.

Eddy-current Loss in Sheet Steel. — The eddy-current coefficient for various makes of ordinary electrical sheets is subject to much the same variation as the hysteresis coefficient, and the same is true for various makes of silicon steel. The values given in the following table are for uniform space distribution of flux and sinusoidal time variation.

VALUES OF EDDY-CURRENT COEFFICIENT †

ϵ = ergs per sec. per cu. cm. for 1 cycle per sec., thickness of 1 cm., and B = 1 gauss.

W_2 = watts per lb. at 60 cycles, thickness of 0.0141 in., and B = 10,000 gausses.

Kinds of sheets	Values of ϵ			Values of W_2		
	From	To	Average	From	To	Average †
Silicon steel........	0.000043	0.000098	0.000065	0.12	0.27	0.180
Ordinary electrical..	0.00012	0.00025	0.00022	0.34	0.70	0.608

* These formulas assume a sine-wave voltage; if the voltage has a form-factor k, multiply the constant K_1 by $\left(\frac{k}{1.11}\right)^2$.

† From tests by L. T. Robinson, *Trans. A. I. E. E.*, *1911*, *Vol. 30*, *p. 741* and Lloyd and Fisher, *Bull. Bur. Stds.*, *1909*, *Vol. 5*, *p. 453*. The "average" values are those given by Mr. Robinson for "standard" and "alloyed iron" respectively.

Eddy-current-loss curves for ordinary electrical sheets are plotted in Fig. 9, and for silicon steel in Fig. 10, these being based on Robinson's values of w_3 and the formula given above, ***which assumes uniform distribution of flux in the sheets and a sine-wave variation with time.*** The numbers on the curves are the gage numbers of the sheets, viz.,

No. 29 gage = 0.0141 inch thick,
No. 26 gage = 0.0188 inch thick,
No. 24 gage = 0.0250 inch thick,

See *Gages, Sheet Metal.*

RELATION BETWEEN FLUX DENSITY AND IMPRESSED VOLTAGE. — When an iron core is magnetized by a current in a coil surrounding it, the flux established is such that the counter e.m.f. set up in the coil is equal to the impressed e.m.f. less the drop in voltage due to the resistance of the coil. The counter e.m.f. may be measured by connecting a voltmeter to the terminals of a secondary coil wound on the same core, provided the flux leakage between the primary and secondary coils is negligible (*see Magnetic Testing*). The counter e.m.f. per turn will be approximately equal to the impressed e.m.f. per turn provided the resistance of the primary winding is small. Let

A = cross-section of core in square inches,
E = effective value of counter e.m.f. per turn, in volts,
f = frequency in cycles per second,
h = form-factor of counter e.m.f. (h = 1.11 for sine wave),
B = maximum flux density in kilolines per square inch.

Then

$$B = \frac{10^5 E}{4hfA}.$$

Effect of Wave Form on Core-Loss. — Experiments by M. G. Lloyd (*Bull. Bur. Stds., 1908, Vol. 5, p. 381*) show that for a given maximum flux density in the core the hysteresis loss is practically independent of the wave form of the counter induced e.m.f. in the exciting coil, provided the voltage wave does not pass through zero more than twice per cycle. This counter e.m.f. is numerically equal to the impressed e.m.f. if the resistance drop in the exciting coil due to the exciting current is negligible, as is the case in a properly designed transformer. However, the maximum value of the flux density established by a given impressed e.m.f. is inversely proportional to the form factor of this e.m.f. (assuming negligible resistance drop). Put

P_h = hysteresis loss for sine-wave voltage,
P_e = eddy-current loss for sine-wave voltage,
P_h' = hysteresis loss for voltage wave having a form factor h,
P_e' = eddy-current loss for voltage wave having a form factor h,
h = form factor of non-sinusoidal wave.

Then for ***given maximum flux density***

$$P_h' = P_h, \qquad P_e' = \left(\frac{h}{1.11}\right)^2 P_e,$$

that is, the hysteresis loss is independent of the form factor and the eddy-current loss varies as the square of the form factor.

For ***given effective value of voltage wave***

$$P_h' = \left(\frac{1.11}{h}\right)^{1.6} P_h, \qquad P_e' = P_e,$$

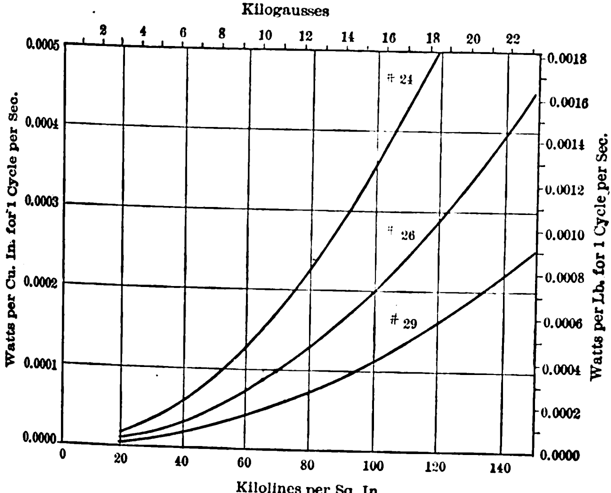

Fig. 9. Eddy-current Loss in Ordinary Electrical Sheet Steel

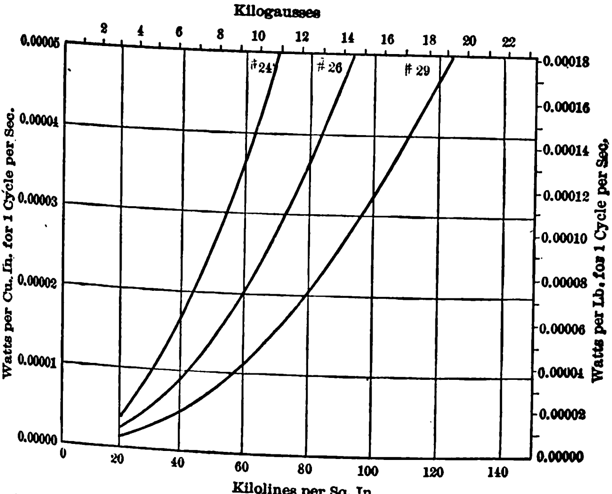

Fig. 10. Eddy-current Loss in Silicon Sheet Steel

that is, the hysteresis loss varies inversely as the 1.6 power of the form factor (approximately only, since the 1.6 "law" is only an approximation to the real facts) and the eddy-current loss is independent of the form factor.

For a given effective value of the voltage wave the total core-loss is therefore less the higher the form factor, i.e., the more peaked the wave.

EXCITING CURRENT ANGLE OF HYSTERETIC ADVANCE.—For a given wave shape of the impressed e.m.f., the wave shape of the exciting current (neglecting eddy currents) is determined by the shape of the hysteresis loop, since the exciting current is proportional to the magnetizing force H. Curve I in Fig. 11 shows the wave shape of the exciting current for a sine wave impressed e.m.f. calculated from hysteresis loop in Fig. 2 for a maximum flux density of 10,000 gausses.

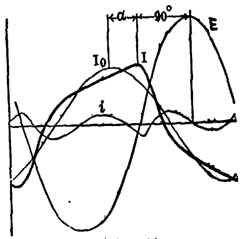

Fig. 11.

The sine curve I_0 is the fundamental of this wave (*see Wave Analysis*), and the curve i is the difference between I and I_0 and consists chiefly of the third harmonic.

The curve E is the sine wave of induced voltage. The flux curve would be a sine curve shifted 90° to the left (ahead of E). The angle α by which the fundamental of the current wave leads the flux wave is called by Steinmetz the "angle of hysteretic advance of phase."

For flux densities below the knee of the B–H curve the effective value of the fundamental current wave I_0 differs but slightly from the effective value of the actual current wave.

In the above discussion the effect of eddy currents is neglected. The effect of these is to increase the exciting current by a component of the same shape as, and in phase with, the impressed e.m.f., thus causing an increase in the effective value of the exciting current and an increase in the angle by which the exciting current leads the flux.

Magnetizing and In-phase Components of Exciting Current.—Let

P_c = total core-loss,
E = back e.m.f. induced in the exciting coil,
I = exciting current,

$$\cos\phi = \frac{P_c}{EI}.$$

Then $I \sin\phi$ is called the magnetizing component of the exciting current and $I\cos\phi$ the in-phase (or energy) component. For magnetizations below the knee of the B–H curve

$$\phi = 90 - \alpha',$$

where α' is the total angle of advance of the exciting current ahead of the flux due to both hysteresis and eddy-current losses.

A.I.E.E., 1911, Vol. 30, p. 761; Lloyd, M. G., *Dependence of Magnetic Hysteresis upon Wave Form*, Bull. Bur. Stds., 1909, Vol. 5, p. 381; also *Bibliography* in article on *Magnetic Testing*.

[H. PENDER.]

MAGNETIC TESTING. — (*See also Electricity and Magnetism, Principles of; Magnetic Properties of Iron and Other Metals.*) The ordinary magnetic tests of iron and other substances are: (1) The determination of the normal *B-H* curves and hysteresis loop, and (2) The determination of the core-losses, i.e., hysteresis and eddy-current losses. The following is a brief table of contents of this article:

DETERMINATION OF THE NORMAL *B-H* CURVES AND HYSTERESIS LOOP. — Under certain conditions, noted below, the magnetizing force *H* may be calculated in terms of the number of turns per unit length and the current. The flux density *B* may be measured in any one of three ways: (1) By winding on the sample a secondary or "test" coil and connecting in series with it a ballistic galvanometer or equivalent device (e.g., a fluxmeter, q.v.) and noting the deflection of this instrument when the current in the primary or "magnetizing" coil is changed in value or reversed; (2) by measuring the mechanical force required to separate one end of the sample from a yoke which, with the sample, forms a closed magnetic circuit; and (3) by measuring the change in resistance of a spiral of bismuth inserted in an air gap between two parts of the sample or between the sample and a yoke. (4) In addition the permeability of two samples may be compared by a device known as a permeability bridge, in which the detector is a magnetometer or compass. These four methods may be designated respectively as the ballistic, traction, bismuth spiral and bridge methods respectively. The first is best suited for precision measurements, the last three for rapid shop tests where great accuracy is not demanded.

Magnetic Circuit of Testing Apparatus. — The simplest form of circuit is a straight bar, which is placed inside a solenoid or helix, the flux returning through the air. With this type of circuit, however, unless the bar and coil are very long, the demagnetizing action of the magnetic poles formed at the ends and along the sides of the bar render it impossible to calculate with accuracy the resultant magnetizing force in the bar. If the sample is made in the form of a closed iron ring, the mean magnetizing force over the cross-section of the metal may be calculated, but unless the radial thickness of the metal is small compared with the radius of the ring, the magnetizing force will be appreciably greater near the inner edge than near the outer edge, and as the permeability is a function of the magnetizing force, an appreciable error may be introduced. Also, the difficulty of winding the coils on a ring makes its use objectionable.

Bar and Yoke. — As a compromise, the sample is usually made in the form of a rod (or bunch of straight strips, in the case of sheet steel) which is fitted into a massive yoke of low reluctance which completes the magnetic circuit. The magnetizing coil is wound on the sample only. As a first approximation, in case the joints between sample and yoke are well made, the reluctance of the yoke and joints may be neglected, and the magnetizing force per unit length of the sample taken as the total magneto-motive force divided by the length of the sample. Methods have been devised for correcting the effect of the yoke and joints as described below.

Demagnetizing the Sample. — After the sample has been mounted ready for test (inserted in the yoke, if a bar and yoke method is employed) the circuit is thoroughly demagnetized by an alternating magnetizing force, preferably of about 1 period per second, which is gradually reduced from an initial intensity which establishes an induction well beyond the point of maximum induction to be measured to a final value somewhat lower than the lowest induction to be measured.

Ordinary Ballistic Method. — The connections are shown in Fig. 1. A ring sample is here shown, but this may be replaced by a straight sample or by a straight bar in a yoke, Fig. 2. The test coil on the sample, the ballistic galvanometer *G*, the secondary coil of the standard solenoid and a resistance *r* are all connected permanently in series. This

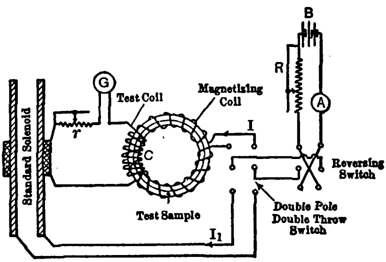

Fig. 1. Connections for Ballistic Method of Measuring Permeability

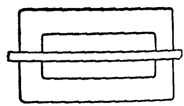

Fig. 2. Bar and Yoke

resistance is adjusted so that the galvanometer shows a suitable deflection when the current in the magnetizing coil of the test sample is reversed. The galvanometer is then calibrated (*see Galvanometers*), keeping this resistance unchanged. A double-pole double-throw switch is provided for connecting the battery circuit at will to the magnetizing coil on the test sample or to the primary coil of the standard solenoid. The sample should be in place when the galvanometer is checked, as the hysteresis and eddy-current losses due to the variable current in the primary during the test have the same effect as an increase in the resistance of the galvanometer circuit. (*See Burrows, C. W., Bull. Bur. Standards, 1909, Vol. 6, p. 31.*)

Precautions. — For a high degree of precision the sample should be placed with its axis perpendicular to the earth's field, the apparatus should be protected from mechanical vibration, and should be sufficiently remote from any strong magnets (such as the permanent magnets in ammeters and voltmeters) in order not to be affected by their magnetic fields.

Calibration of Galvanometer. — Let

N_1 = number of turns in primary of standard solenoid *per centimeter length* (axial),
n_1 = total number of turns in secondary coil of standard solenoid,
n = total number of turns in secondary coil on test sample,
A_1 = mean cross-section, in square centimeters of primary coil of standard solenoid if secondary is on the outside; if the secondary is inside the primary A_1 is the mean cross-section of the secondary,
A = cross-section in square centimeters of the test sample,
a = mean cross-section in square centimeters of the magnetizing coil on test sample if the test coil is on the outside; if the test coil is on the inside a is the mean cross-section of the test coil,
I_1 = current established through primary of solenoid,
D = deflection of galvanometer when this current is reversed,

B = flux density in test sample corresponding to a deflection D when the current through the magnetizing coil on the sample is reversed,

H = magnetizing force in sample corresponding to the flux density B.

The flux in maxwells established by the current I_1 through the primary of the solenoid is then $0.4\pi N_1 I_1 A_1$, and the number of linkages of this flux with the secondary of the standard solenoid, i.e., with the galvanometer circuit, is $0.4\pi n_1 N_1 A_1 I_1$. When the double-throw switch is thrown to connect the battery to the magnetizing coil on the test sample, establishing in this coil a current I and a flux density B, the number of linkages between the flux in the test sample and the galvanometer circuit will be $BnA + Hn\ (a - A)$. If these two linkages are equal, as they will be if the galvanometer shows the same deflection D when I is reversed through the magnetizing coil on the test sample as when I_1 is reversed in the primary of the solenoid, then

$$B = \frac{0.4\pi n_1 N_1 A_1}{nA} I_1 - \frac{a - A}{A} H. \qquad (1)$$

Or, putting

$$K = \frac{0.4\pi n_1 N_1 A_1}{nA},$$

which is a constant for a given solenoid and sample, then

$$B = KI_1 - \frac{a - A}{A} H. \qquad (2)$$

The correction term $\left(\frac{a - A}{A}\right) H$ is usually negligible except for very low values of the flux density.

Hence, by sending various currents I_1 through the primary of the solenoid, reversing these currents and noting the deflection D, a curve may be plotted showing the relation between B ($= KI_1$) and D. Then, when a given current is reversed through the magnetizing coil on the test sample and the deflection D noted, the flux density corresponding to this current may be read directly from the curve. This curve will be practically a straight line unless the damping of the galvanometer is excessive.

The calibration curve holds only for a constant total resistance in the galvanometer circuit (*see Galvanometers*). If it is necessary to change this resistance in order to alter the sensibility of the galvanometer a new calibration curve must be obtained.

Calculation of Magnetizing Force. — Let

N = number of magnetizing turns per centimeter of mean circumference (*see Fig. 1*). If a straight sample with or without a yoke is used, N is taken as the total number of magnetizing turns divided by the free length of the sample in inches.

I = current in magnetizing coil in amperes.

Then the magnetizing force in gilberts per centimeter is

$$H = 0.4\pi NI. \qquad (3)$$

This formula represents the *average* magnetizing force over the section of the ring, if a ring sample is used. If a straight sample is used, the formula is approximate only, due to the reluctance of the return circuit through the air or yoke.

Determination of Normal B–H Curve by Ballistic Method. — The sample is first demagnetized as described above, then the lowest magnetizing force to be used is applied and reversed many times until the iron is brought to

a cyclic magnetic state, that is, until the reversal of the magnetizing force reverses the direction of magnetization without changing its magnitude. The number of reversals required to establish a cyclic condition in soft steel ranges from about 10 at high flux densities to several hundred at low flux densities. In general the harder the steel the fewer the number of reversals required. The galvanometer deflection is then noted, and the corresponding value of B taken from the calibration curve and H calculated from the formula given above. As a check, it is well to carry the iron through the demagnetizing process again, reduce to a cyclic state, and redetermine the point.

Higher points on the curve may be obtained in a similar manner, but it is not necessary to demagnetize the sample between successive points unless it accidentally becomes magnetized above the point being determined.

Determination of Hysteresis Loop by the Ballistic Method.—The sample is first demagnetized and then the maximum magnetizing force (corresponding to the tip of the loop) is applied and a cyclic condition established as described in the preceding paragraph. By suddenly inserting an additional resistance in the magnetizing circuit, e.g., by moving the slider on the resistance R so that less of this resistance is short-circuited, the magnetizing force is reduced to any desired value, and the change in flux density corresponding to this change in magnetizing force is determined by noting the galvanometer deflection. If the calibration curve of the galvanometer has been obtained by the method of reversals, as described above, the change in flux density is twice the value of B as read from the calibration curve, since the actual change in flux corresponding to any ordinate of the calibration curve is twice this ordinate.

The next point on the hysteresis loop is determined in the same manner, first bringing the iron to a cyclic state under the maximum magnetizing force corresponding to the tip of the loop. Data with negative values of the magnetizing force are obtained by reversing the currents in addition to making the adjustments already described. The points on the hysteresis curve may be taken in any order.

In this method of obtaining hysteresis data, the measured quantity is the change in induction when the magnetization is changed at one step from a maximum to any other given point on the hysteresis loop. This method is comparatively free from the irregularities due to the slow creep that occurs when a magnetizing force is applied slowly or changed by small steps. It is also free from irregularities due to variations in the size of step in the "step-by-step" method, in which the magnetizing force is changed from one value to the next lower without restoring it each time to the maximum value. (*See Burrows, Bull. Bur. Standards, 1909, Vol. 6, p. 1.*)

Zero Ballistic Methods for Determining Flux Density.—By using an independent battery circuit to energize the primary of the standard solenoid and establishing the currents I_1 and I at the same time and reversing them simultaneously, it is possible by having the relative directions of these currents right, so to adjust I_1 that for a given value of I the net discharge through the galvanometer is zero, and no deflection occurs. Under this condition B may be calculated directly from equation (1) or (2) above.

Instead of using a standard solenoid with fixed coils, an adjustable mutual inductance, previously calibrated, may be used, and a constant current maintained through its primary, the adjustment being effected by moving the secondary. Let

M = mutual inductance of standard, in henries,
I = current in amperes, in primary of mutual inductance,
n = total number of turns in test coil on sample,

A = cross-section of sample in square centimeters,
B = flux density in sample for balance.

Then

$$B = 10^8 \frac{MI}{nA} = K_1 M,$$

where $K_1 = \frac{10^8 I}{nA}$ = a constant for a given test coil and sample and given current in the primary of the mutual inductance.

The design of a standard mutual inductance suitable for this purpose is described in detail by Burrows, *Bull. Bur. Stds., 1909, Vol. 6, p. 31.*

Burrows' Compensated Double-Yoke Method. — This method, described in detail in Vol. 6 of the Bulletins of the Bureau of Standards (*Reprint No. 117*), is the standard method used by the Bureau of Standards and has also been adopted as the standard method of testing permeability by the American Society for Testing Materials, see *Proc. Am. Soc. Test. Mat., 1912.* The following description of the method is taken from Burrows' paper.

Fig. 3 shows the relative positions of the magnetizing and test coils when double yokes and double rods are used. The lower rod is the one under test.

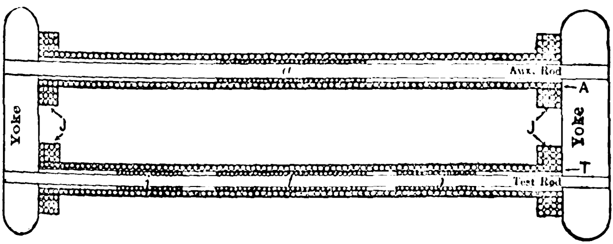

Fig. 3. Double Yoke and Bars

The upper rod is an auxiliary rod of approximately the same magnetic properties as the test specimen. T and A are the two main magnetizing coils, one wound over each rod. Over the four joints are wound four short coils J, each about 1.5 centimeters long. These are connected in series and used as a single coil. t and a are the two test coils surrounding test and auxiliary specimen respectively. j is the end test coil distributed with one-half over each end of the test rod.

Test Samples. — When rods are to be tested these should preferably be of square cross-section, ⅜ by ⅜ inch (0.9525 cm.) and 30 cm. long. With rods of square cross-section it is possible to make a more perfect joint between the rods and yokes. Sheet steel is tested by making up two equal bundles of strips 3 centimeters wide by 50 centimeters in length, having a total weight of 5 kilograms (*Stand. Spec. of Am. Soc. Test. Mat., June, 1912*). Each bundle will be about 2.25 centimeters thick. One bundle takes the place of the test rod, the other takes the place of the auxiliary rod.

Yokes. — The yokes are of soft iron, provided with suitable clamps for holding the sample firmly and making a good magnetic joint. When sheet steel is being tested, the yokes may be made of short strips of the material 3 centimeters wide, the magnetic circuit in this case being a rectangle made up of strips, the joints at the four corners being alternately butt and lap in successive layers.

Magnetizing Coils. — No. 18 A. W. G. double-cotton-covered copper wire is a convenient size. A coil made of ten layers of this wire will stand continu-

ously a current of 1.7 amperes, corresponding to a magnetizing force of $H =$ 171 gilberts per centimeter. For short periods twice this current may be safely employed, giving a magnetizing force of about 350 gilberts per centimeter. The length and diameter of the coils will depend upon the dimensions of the test sample (see above). If the coils are made of round cross-section the hollow core on which they are wound should have a shallow screw thread, 8 threads to the centimeter, cut on the outside. The first layer is wound in this thread, and succeeding layers wound in the same direction between adjacent wires in the previous layer. The various layers are then connected in series. The magnetizing force at the center of such a coil of ten layers, assuming perfect compensation for the rest of the magnetic circuit, is

$$H = 0.4\pi \times 8 \times 10 I = 100.53 I,$$

where I is the current in the coil.

Test Coils.—The test coils are made of fine wire (enameled or silk covered) wound on thin cores of paper, cloth or slotted metal. Coils t and a are placed over the middle portions of the test rod and auxiliary rod, respectively. Over the two ends of the test rod are placed the two halves of a third test coil j. These three test coils have the same number of turns and are spread over a considerable length of rod, so as to prevent any irregularities which may exist in the iron from exerting a preponderating influence. If the test coils are placed inside the magnetizing coils the correction for the flux between the rod and the coil will be small.

Connections for Permeability Test.—Fig. 4 shows diagrammatically the full scheme of electric circuits both primary and secondary. The coils T, J, A, t, j and a are the same as those of the same letters in Fig. 3. The coils M and m are the primary and secondary of the variable mutual inductance (or standard solenoid) used to balance the e.m.f. induced in the test coil.

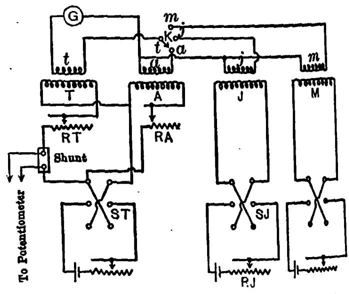

Fig. 4. Connections for Burrows' Method of Testing Permeability

Compensation.—Compensation is secured when the flux across every section of the iron circuit is the same, i.e., when there is no leakage. This condition may be closely realized by adjusting the currents in the three magnetizing coils separately.

The switches ST and SJ are reversed repeatedly, and the resistance RA and RJ adjusted until the three test coils, t, j and a, indicate the same change in flux when the magnetizing currents are simultaneously reversed, i.e., switches ST and SJ reversed simultaneously. With the key K on the point t–a, the equality of flux in the test and auxiliary rods is secured first by adjusting RA until the galvanometer shows no deflection on reversing ST. Then with the key K on the point t–j the flux near the magnetic joints is adjusted to uniformity.

Measurement of Induction.—To measure the induction, K is moved to the point t–m. A reversal of the magnetizing forces produces an impulsive electromotive force acting on the galvanometer, which may be measured as a deflection or may be compensated for by reversing simultaneously a suitable current through a variable mutual inductance, or standard solenoid M.

Measurement of Magnetizing Force. — For accurate work the current should be measured by means of a potentiometer (*see Potentiometers*). If the shunt used for measuring the current has a resistance of 1.0053 ohms and the magnetizing coil T 80 turns per centimeter, then

$$H = 100\ V,$$

where V is the fall of potential across this shunt.

STANDARD INDUCTION TESTS OF THE A.S.T.M. (*adopted June 1, 1912, by the American Society for Testing Materials.*)

The normal magnetic induction is the induction produced by a magnetizing force in a given piece of magnetic material which has been previously demagnetized and then subjected to many reversals of the given magnetizing force.

Both the induction B and the magnetizing force H shall be expressed in terms of the C. G. S. electromagnetic unit (gauss).

Sheet Metal. — The standard normal induction data for sheet material shall consist of the magnetizing forces corresponding to inductions of 2000, 4000, 6000, 8000, 10,000, 12,000, 14,000, 16,000, 18,000, 20,000 gausses, or such as may be obtained without exceeding a magnetizing force of 200 gausses.

The following details are to be observed.

The test material shall consist of 5 kilograms of the strips cut as indicated for the standard core-loss test.

The magnetic circuit shall be a rectangle having the test material for one pair of opposite sides, and the same or different material for the other pair, which may be shorter. The joints at each corner are alternately butt and lap, or may be clamped on the edges.

The magneto-motive force is applied in two sections. The main magnetizing coils shall consist of two equal and uniformly-wound solenoids surrounding the test material. The compensating coils shall consist of four short coils, each having the same number of turns wound closely over the ends of the magnetizing coils.

The test coil surrounds the middle portion of each bundle of test material. Four other test coils of half the number of turns are placed over the test material, approximately midway between the yokes and the center. (This arrangement is similar to Fig. 3 except that two additional test coils corresponding to j are used on the upper bundle.) The two center test coils are joined in series and the four test coils are joined in series. The corresponding ballistic deflections, due to these two test coils, are measures of the magnetic fluxes through the underlying portions of the magnetic circuit. By connecting the two test coils so that the induced electromotive forces oppose each other, and adjusting the current through the compensating magnetizing coils so that there is no resulting ballistic deflection, an approximate uniformity of flux is secured through the greater portion of the test material, and the induction may be measured ballistically in the regular manner. The magnetizing force when the flux is adjusted to uniformity is that calculated from the uniform winding of the main magnetizing solenoids.

The cross-section of the magnetic circuit is determined as in the standard core-loss test.

Rods. — The standard test for rods for use in electromagnets shall consist of the magnetizing forces corresponding to inductions of 2000, 4000, 6000, 8000, 10,000, 12,000, 14,000, 16,000, 18,000, 20,000 gausses, or such as may be obtained without exceeding a magnetizing force of 200 gausses.

The standard test for rods intended for permanent magnets shall consist in the measurement of the magnetizing force, the residual induction and the coercive force corresponding to a maximum induction of 14,000 gausses.

Standard tests shall be made by the Burrows compensated double-yoke method (*described above, and also in Technical Paper No. 117 of the Bureau of Standards*).

Permeability Bridge. — A double-bar and yoke arrangement, such as shown in Fig. 3, may be used without compensating or test coils to obtain a fairly accurate measure of the permeability of a sample, provided the B–H curve of one of the rods is known. A small magnetic needle or compass placed in the air-space between the two rods is used as a detector of magnetic leakage from one rod to the other. The currents in the two magnetizing coils are adjusted until the needle shows no deflection when the currents in the two coils are reversed. The total flux in each rod will then be the same. The magnetizing forces in the two rods are then calculated from the currents in the magnetizing coils (*equation 3 above*) and the flux from the B–H curve of the standard sample.

PERMEAMETERS FOR SHOP TESTS. — A great number of approximate methods have been devised for the rapid testing of permeability in shop work, where a high degree of precision is not required. Some of these are briefly described below.

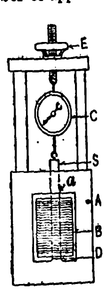

Fig. 5. Thompson Permeameter

Thompson Permeameter (Fig. 5). — In this instrument the flux density is measured in terms of the force required to separate a rod S from a yoke A, when the magnetic circuit formed by the rod and yoke is magnetized by a current in the coil B. The handle E is turned until the sample is pulled away from the yoke and reading on the balance taken at the instant of break.

Let

I = amperes in magnetizing coil,
N = number of turns in magnetizing coil,
l = "equivalent" length of magnetic circuit in inches = distance from a to D plus from 10 to 20 per cent to allow for reluctance of yoke and joints,
P = pull in pounds as read by balance,
A = cross-section of rod S in square inches.

Then the magnetizing force is

$$H = \frac{0.4\pi NI}{2.54\,l},$$

and the flux density is, within the accuracy of measurement by the instrument,

$$B = 1320\sqrt{\frac{P}{A}}.$$

There are several errors in the instrument, however, notably the unavoidable air gap between the sample and the top of the yoke and the contact at D, which makes the instrument unsuitable for the accurate determination of the absolute values of the qualities of iron and steel. It is, however, extremely useful for the comparison of samples where exact absolute values are not required. More nearly absolute values can be obtained by properly calibrating the instrument by using a standard sample the permeability of which at various flux densities has been measured by a more accurate method.

Du Bois Permeameter (Fig. 6). — Another form of traction permeameter is that devised by Du Bois.

The tractive force is measured across a gap in a yoke which completes the magnetic circuit of which the sample or test piece forms part. In the figure P and P_1 are massive soft-iron pole pieces in which the sample S is clamped.

A is a yoke pivoted at *E*. *B* is the magnetizing coil. The resultant moment acting on the balance when a flux is established across the gaps *G* and G_1 is a function of the flux density in the sample (all samples are of the same cross-section). Consequently, the point on the scale at which the weight *W* must be placed for a balance is a measure of the flux density. The scale is calibrated to read directly in flux densities. Due to the reluctance of the yokes and air gaps a correction factor, furnished with the instrument, must be used to obtain the magnetizing force from the ordinary formula.

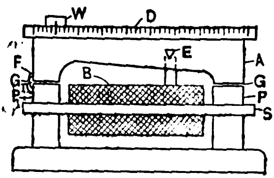

Fig. 6. Du Bois Permeameter

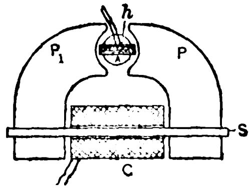

Fig. 7. Koepsel Permeameter

Koepsel Permeameter (Fig. 7). — The magnetic circuit consists of the sample *S* and two heavy soft-iron pole pieces *P* and P_1, with a gap and soft-iron core *A* (similar to the gap and core in the voltmeter). A small coil *h* is suspended in the gap and connected to an auxiliary current supply. The sample is magnetized by current passing through the magnetizing coil *C*. The flux produced in the magnetic circuit causes the coil *h* to deflect an amount proportional to that flux, for a constant strength of auxiliary current. The deflection is indicated by a pointer, attached to the coil *h*, swinging over a scale that is calibrated to read directly in flux densities. The calibration of the instrument does not hold for wide variations in the permeability of the samples since the leakage depends upon this permeability. Also the magnetizing force can be calculated only approximately. These difficulties can be overcome in a measure by placing compensating coils on the yokes *P* and P_1 and sending sufficient current through these to compensate for the leakage.

Esterline Permeameter. — This instrument is similar to the Koepsel apparatus except that the moving coil and core (*h* and *A* in Fig. 7) are replaced by a small direct-current armature. The apparatus then becomes a small separately-excited dynamo. The armature is driven by an auxiliary motor at a constant speed. The voltage across the armature is then directly proportional to the total flux cutting the armature conductors. Leakage is avoided by the use of compensating coils on the pole pieces. The current in these compensating coils is adjusted until a small compass placed near the magnetic circuit of the apparatus shows no deflection when the magnetizing and compensating currents are simultaneously reversed. The apparatus is described in detail in *Proc. Am. Soc. Test. Mat.*, 1906, Vol. 6, p. 320.

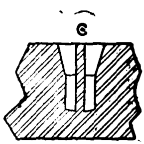

Fig. 8. Drilled Hole for Drysdale Permeameter

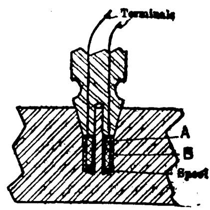

Fig. 9. Drysdale Permeameter

Drysdale Permeameter (Fig. 9). — This device is particularly useful in determining the permeability of large generator frame castings or other large

masses of metal without the preparation of samples. A hole is drilled in the casting at any point desired with a special drill that will leave a hole with a core in the center similar to that shown at *C* in Fig. 8.

A magnetizing coil *A* and a test coil *B* are wound on a soft-iron plug and inserted into this hole as shown. The terminals of both these coils are brought out through small holes in the plug. Measurements are made by the ordinary ballistic method.

Bismuth Spiral. — Bismuth has the property of changing in electrical resistance when put in a magnetic field. The per cent increase in resistance in bismuth when in a magnetic field is nearly proportional to the magnetic density of the field. For measuring permeability, a flat spiral of bismuth wire non-inductively wound is fastened between two plates of mica, the terminals of the coil being brought out through a long insulated handle.

The sample is made in two pieces and held in a yoke such as shown in Fig. 2. The two rods are inserted through the holes in the ends of the yoke and are pushed in until only a small air gap is left between their opposing ends. The bismuth spiral is inserted in this gap. The resistance of the spiral is measured with a Wheatstone's bridge and the flux density determined from a curve furnished with the spiral giving the variation in resistance with varying density. The calculated value of the magnetizing force must be corrected for the reluctance of the yoke and air gap.

CORE-LOSS MEASUREMENTS. — A great number of methods have been suggested for determining the core-loss in a sample of iron or steel when subjected to an alternating field. These methods may be classified as: (1) hysteresis loop method; (2) wattmeter method; (3) mechanical torque methods. Of these the wattmeter method, when a properly constructed magnetic circuit is employed, gives the most reliable results. The hysteresis loop method is tedious and gives no knowledge of the eddy-current loss. The mechanical torque methods necessitate an air gap in the magnetic circuit with a resulting induction in the specimen which is far from uniform; these latter methods, however, are frequently used where high degree of accuracy may be sacrificed to speed in testing, e.g., in comparative shop tests.

Hysteresis Loss from Hysteresis Loop.—The hysteresis loop may be determined by any of the methods described above. The loop is plotted on cross-section paper and integrated. Plot the magnetizing force, in gilberts per centimeter, to a scale of h gilberts per centimeter equal to 1 inch and the flux density to a scale of b gausses equal to 1 inch. Then if A is the area of the loop in square inches, the hysteresis loss, in ergs per cycle per cubic centimeter of iron, is

$$W = \frac{hbA}{4\pi}.$$

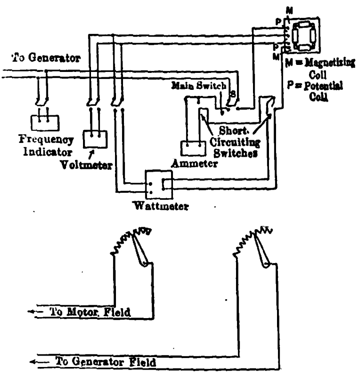

Fig. 10. Connections for Core-loss Tests

Principle of Wattmeter Method of Determining Core-Loss. — Fig. 10 is a complete diagram of connections. The principle of this method is as follows: The sample to be tested is inserted in a magnetizing coil of a known number of

turns, under* which is wound a secondary coil having either the same number of turns or a multiple thereof. The primary coil is connected in series with a source of alternating e.m.f. (which can be adjusted without changing its wave form) and the current coil of a wattmeter. The potential coil of the wattmeter is connected to the secondary coil on the test sample. A voltmeter is also connected across this secondary coil.

Let

N_1 = number of primary turns,
N_2 = number of secondary turns,
A = cross-section of sample in square centimeters,
f = frequency in cycles per second,
k = form factor of secondary voltage,
B = maximum flux density in sample, assumed constant throughout its length,
V = reading of voltmeter,
P = reading of wattmeter,
$R = r + \frac{R_1 R_2}{R_1 + R_2}$, where r is the resistance of the secondary coil, R_1 the resistance of the voltmeter and R_2 the resistance of the potential coil of wattmeter.

The resistance R should be sufficiently large so that the heat developed (V^2/R) in the secondary circuit is small compared to the core-loss, and the resistance r of the secondary coil should also be small compared with R. Then if the instruments are calibrated to read correctly and P and V are read simultaneously, the total core-loss is, assuming r negligible compared with R,

$$P_c = \frac{N_1}{N_2} P - \frac{V^2}{R},$$

and the maximum flux density is

$$B = \frac{10^8 V}{4 kfAN_2}.$$

Test Specimen with Single Coil. — The core-loss test can also be made with a single coil (the magnetizing coil) on the sample with the voltmeter and potential circuit of the wattmeter connected to the terminals of this coil. In this case, however, the voltage read by the voltmeter must be corrected for the resistance drop in the magnetizing coil, and the wattmeter reading for the rI^2 loss in this coil. The two-coil method also has the advantage that the wattmeter reading can be made any multiple of the actual loss by using a proper ratio of N_2/N_1, thus enabling one to measure small losses with greater accuracy.

Control of Impressed E.M.F. — The e.m.f. impressed across the terminals of the magnetizing coil should have a sine wave form for all values of the maximum flux density at which tests are to be made. To secure this condition it is necessary that the e.m.f. of the generator supplying the current have a sine wave form, and that the resistance and reactance of both the generator and the circuit between the generator and the test sample be as small as possible, as the magnetizing current, having a distorted wave form due to hysteresis (see *Magnetic Properties of Iron*), will introduce a voltage drop having a non-sine form, thus distorting the impressed voltage wave.

The impressed voltage should therefore be controlled through the field of a generator having a large capacity compared to the power taken by the test sample, or instead of varying the field a transformer with suitable taps may be used, provided the resistance and leakage reactance of the transformer are small.

* The two windings may also be "sandwiched."

In either case, the generator should give a sine wave at all field excitations within the range used. If this condition cannot be realized the hysteresis and eddy-current losses should be separated by measuring the total loss at two frequencies and the total loss then corrected for form factor (see below).

Form of Specimen for Wattmeter Test. — The specimen may have one of three forms: (1) It may be in the form of straight strips, the flux lines returning through the air; (2) straight strips may be used with a yoke; and (3) the specimen may be arranged to form a closed magnetic circuit in itself.

The first form gives a distribution of flux which is far from uniform. It is possible, however, by determining the flux distribution in the sample by means of an exploring coil to correct the observed losses for this flux variation (*see Robinson, L. T., Trans. A.I.E.E., 1911, Vol. 30, p. 741*).

The second form gives a more uniform flux, but it is necessary to distinguish between the energy supplied to the specimen and that supplied to the yoke. This can only be done satisfactorily by knowing the constants of the yoke, and only then by having the distribution of flux uniform, a condition difficult to secure.

Consequently, for accurate measurements the third form is the most reliable, although for factory use the first or second may prove more convenient where accuracy can be sacrificed for other considerations. The material used should be cut in a form such that only a small part of it is contiguous to a cut edge since all methods of cutting have a hardening effect upon the material bordering upon the cut. This means that the strip, whether straight or in ring form, should not be too narrow. This condition may be dispensed with if all specimens are annealed under definite conditions after cutting to size, and prior to testing.

Two general forms of magnetic circuit are available. The material may be stamped into rings (as in the Esterline apparatus), or the circuit may be built up from straight strips as in the Epstein apparatus. Leakage is most effectually avoided by using rings. With this form of specimen, however, the flux density will not be uniform unless rings of very great diameter are employed, and in the latter case there is a very great waste of material. The non-uniformity of flux existing in rings of small diameter, even when uniformly wound, and the errors resulting therefrom, are discussed by Loyd, M. G., *Bull. Bur. Stds., 1909, Vol. 5, p. 435*. The use of rings is thus restricted to cases where the material is annealed after stamping, and the radial width of the ring should be very small in comparison to its diameter. When rings are employed, the labor of winding each specimen separately with a magnetizing coil may be obviated by the use of the apparatus of Esterline (*see p. 925*) or Möllinger (*E. T. Z., 1901, Vol. 22, p. 379*).

Epstein Method. — This method has been adopted as the standard in Germany and by the American Society for Testing Materials in this country. It is used for commercial testing by both the General Electric and Westinghouse Companies. The method is clearly described in the standard specifications for making core-loss tests given in the following paragraph.

A.S.T.M. Standard Core-loss Tests. (Adopted June 1, 1912 by the *American Society for Testing Materials*.)

The power consumption in electrical sheet steel when subjected to an alternating magnetization is known as the core-loss. The standard core-loss is the total power in watts consumed in each kilogram of material at a temperature of 25° C., when subjected to a harmonically-varying induction having a maximum of 10,000 gausses and a frequency of 60 cycles per second, when measured as specified below. It is represented by the symbol $W_{10/60}$.

The ageing coefficient is the percentage change in the standard core-loss after continued heating at 100° C. for 600 hours.

The standard core-loss shall be measured under the following conditions:

The magnetic circuit consists of 10 kilograms (22 pounds) of the test material, cut with a sharp shear into strips 50 centimeters (19 11/16 inches) long and 3 centimeters (1 3/16 inches) wide, half parallel and half at right angles to the direction of rolling, made up into four equal bundles, two containing material parallel and two containing material at right angles to the direction of rolling, and finally built into the four sides of a square with butt joints and opposite sides consisting of material cut in the same manner. No insulation other than the natural scale of the material (except in the case of scale-free material) shall be used between laminations, but the corner joints shall be separated by tough paper 0.01 centimeter (0.004 inch) thick.*

The magnetizing winding shall consist of four solenoids surrounding the four sides of the magnetic circuit and joined in series. A secondary coil shall be used for energizing the voltmeter and the potential coil of the wattmeter.

These solenoids shall be wound on a form of any non-magnetic non-conducting material of the following dimensions:

Inside cross-section...........................	4 by 4 cm.
Thickness of wall	not over 0.3 cm.
Winding length............................	42 cm.

The primary winding on each solenoid shall consist of 150 turns of copper wire uniformly wound over the 42-centimeter length. The total resistance of the magnetizing winding shall be between 0.3 and 0.5 ohm. The secondary winding of 150 turns of copper wire on each solenoid shall be similarly wound beneath the primary winding. Its resistance shall not exceed 1 ohm.

A voltmeter and the voltage coil of a wattmeter shall be connected in parallel to the terminals of the secondary winding of the apparatus. The current coil of the wattmeter shall be connected in series with the primary winding.

A sine-wave electromotive force shall be applied to the primary winding and adjusted until the voltage of the secondary circuit is given by the equation,

$$E = \frac{4fNkBM}{4lD\,10^8},$$

in which

k = form factor of primary e.m.f. = 1.11 for sine wave,
N = number of secondary turns = 600,
f = number of cycles per second = 60,
B = maximum induction = 10,000,
M = total mass in grams = 10,000,
l = length of strips in centimeters = 50,
D = specific gravity = 7.5 for high-resistance steel
= 7.7 for low-resistance steel,
E = 106.6 volts for high-resistance steel for sine voltage
= 103.8 volts for low-resistance steel for sine voltage.

* The purpose of this paper is to prevent the exposed end of the laminations being forced into the spaces between those in the adjacent side of the other part of the sample and to prevent the formation of eddy currents at the corners which may not be confined to the thickness of the laminations if the paper is not used. The certainty of the measurements is thereby improved by a small but definite amount over the results which are obtained without the paper in the joints. This improvement is of course accomplished at the expense of some increase of leakage flux at the corners and consequently greater departure from absolute uniformity of flux distribution along the length of the sample, also the conditions imposed upon wattmeter are more severe as the general power factor is lower. The flux distribution over a section of the sample is more uniform with the paper. The net result is a definite gain in accuracy.

(L. T. Robinson.)

A specific gravity of 7.5 is assumed for all steels having a resistance of over 2 ohms per metergram, and 7.7 for all steels having a resistance of less than 2 ohms per metergram. These steels are designated as high- and low-resistance steels, respectively.

The wattmeter gives the power consumed in the iron and the secondary circuit. The loss in the secondary circuit is given in terms of the total resistance and voltage. Subtracting this correction term from the total power gives the net power consumed in the steel as hysteresis and eddy-current loss. Dividing this value by ten gives the core-loss in watts per kilogram.

The Procedure. — 1. Cut from the test material a number of strips 3 by 50 centimeters, half parallel and half at right angles to the direction of rolling.

2. Place on the balance a pile of strips weighing 2.5 kilograms. Add a second pile of the same kind, bringing the weight up to 5 kilograms. In each case the weight is taken to the nearest strip. Add in succession two piles of 2.5 kilograms each, of the other kind of strips, bringing the weight up to 7.5 kilograms and 10 kilograms respectively.

3. Secure each bundle by string or tape (not wire) and insert in the apparatus as indicated.

4. Apply the alternating voltage to the primary coil and tap the joints together until the current has a minimum value, as shown by an ammeter in series. Then clamp the corners firmly by some suitable device.

5. Shunt the ammeter and adjust the primary current until the voltmeter indicates the proper value. This adjustment may be made by an auto-transformer by varying the field of the alternator, or by both, but not by the insertion of resistance or inductance in the primary circuit. Simultaneously the frequency must be adjusted to 60 cycles.

6. Read the wattmeter.

7. Calculations. Subtract from the wattmeter reading the instrument losses, which will be constant for any set of instruments and voltage, and divide by 10. The result is the standard core-loss.

Bureau of Standards' Method. — (*Bull. Bur. Stds., 1909, Vol. 5, p. 453; Trans. A.I.E.E., 1909, Vol. 28, p. 439.*) This is a modification of the Epstein method. It differs from the latter in the use of a smaller test specimen, from 1.5 to 2 kilograms (about 4 pounds) of strips 25.4 by 5 centimeters (10 by 2 inches), and in the use of a different form of joint between the four bundles of strips. In other respects it is essentially the same as the Epstein method.

Fig. 11 shows the arrangement of the joint. At the corners of the square, short pieces of test material are bent at right angles and interleaved between the strips of adjacent bundles, as shown in the figure. There are as many of

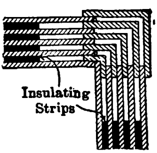

Fig. 11. Detail of Joint Used by N.B.S.

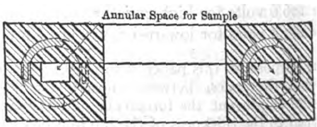

Fig. 12. Esterline Apparatus

these corner pieces as there are test pieces, and they are graduated in length so as to give a uniform lap of about 2 millimeters. A special clamp is tightened over these laps, so as to give a good magnetic joint. The object of these corner pieces is to reduce the leakage and thereby obtain a more nearly uniform flux

throughout the sample. The loss in these corner pieces is small and can be calculated to a sufficient degree of accuracy and allowed for.

Esterline Apparatus For Testing Iron Rings (Fig. 12). — This apparatus is designed for testing rings made up of punchings from sheet steel. It is essentially a solenoid made in the form of a doughnut, but divided into two halves. The sample is inserted by lifting off the top half; the top half is then replaced and the teeth formed by the projecting ends of each upper half-turn fit into little sockets formed at the ends of the corresponding lower half-turn. (*Esterline, J. W., Proc. Am. Soc. Test. Mat., 1906, Vol. 6, p. 320.*)

Ewing Hysteresis Tester. — Strips 5/8 by 3 inches are cut from the sheets to be tested and a bundle of about 7 is used in each test. This sample is rotated at a relatively low speed (to avoid eddy currents) between the poles of a permanent magnet, the magnet being pivoted at the center of rotation and carrying a pointer that deflects over a scale, the deflection depending on the hysteresis loss in the sample. Two standard samples of known hysteresis properties are furnished with the instrument, so that the scale may be calibrated from time to time.

The Blondel Hysteresis Tester. — This apparatus is similar in principle to the Ewing hysteresis tester, but the magnet is revolved instead of the sample. The samples are made in the form of rings which are mounted on a pivoted spindle between the poles of a U-shaped permanent magnet. When the magnet is revolved the sample tends to follow it but is restrained by a spiral spring, and therefore it turns only through an angle such that the torque due to the hysteresis loss is balanced by the opposing torque of the spring.

The Holden-Esterline Core-loss Tester. — This instrument is similar to the Blondel hysteresis tester previously described but an electromagnet is substituted for the permanent magnet and this magnet is driven by a motor at the required frequency. The spring is arranged with a torsion head and pointer that is set to zero when the instrument is not in use.

The angle of torsion necessary to bring the sample back to its zero position when the instrument is operating is read on a scale calibrated directly in watts loss. The speed of rotation being high the eddy-current losses are appreciable, and therefore the instrument reads the combined loss due to hysteresis and eddy currents at the frequency corresponding to the speed of rotation.

SEPARATION OF HYSTERESIS AND EDDY-CURRENT LOSSES. — The total loss is measured by the wattmeter method at two frequencies, say f_1 and f_2, but at the *same effective voltages*. Let

P_1 = total loss at frequency f_1,
P_2 = total loss at frequency f_2,
h_1 = form factor at frequency f_1,
h_2 = form factor at frequency f_2,
E_1 = effective value of induced e.m.f. at frequency f_1,
E_2 = effective value of induced e.m.f. at frequency f_2,
K_h = hysteresis loss at 1 cycle per second and sine wave e.m.f. of 1 volt,
K_e = eddy-current loss at 1 cycle per second and e.m.f. of 1 volt.

Then for a given iron core (*see article of Magnetic Properties of Iron*)

$$P_1 = \left(\frac{1.11\,E_1}{h_1}\right)^{1.6} f_1 K_h + (f_1 E_1)^2 K_e,$$

$$P_2 = \left(\frac{1.11\,E_2}{h_2}\right)^{1.6} f_2 K_h + (f_2 E_2)^2 K_e,$$

whence, by measuring all the other quantities, K_h and K_e may be calculated from these two equations. This method of separation, however, assumes 1.6 as the hysteresis coefficient, which is an approximation.

However, if a sine wave e.m.f. of the same effective value is used at both frequencies, the separation can be made without any other assumption than that the hysteresis loss varies directly as the frequency and the eddy-current loss as the square of the frequency, both of which conditions are in accord with fact when the frequency is less than 100 cycles per second and ordinary thicknesses of sheets are used.

In particular, if f_2 is taken as one-half of f_1 as well as $E_1 = E_2$, both in effective value and wave form, then

$$\text{Eddy-current loss at frequency } f_1 \quad = f_1^2 K_e \; E_1^2 = 2\,(P_1 - 2\,P_2),$$
$$\text{Hysteresis loss at frequency } f_1 \quad = f_1 K_h \; E_1^{1.6} = 4\,P_2 - P_1,$$

and these relations are independent of the law of variation of the hysteresis loss with maximum flux density.

IRON-LOSS VOLTMETER. — As pointed out in the article on *Magnetic Properties of Iron*, the core-loss depends upon the form of the impressed voltage wave. The dotted curves A, B and C in Fig. 13 show the variation in core-loss with form factor when the eddy-current loss is 14 per cent, 20 per cent and 30 per cent of the total loss. The loss corresponding to a sine-wave voltage (form factor 1.11) is taken as 100 per cent.

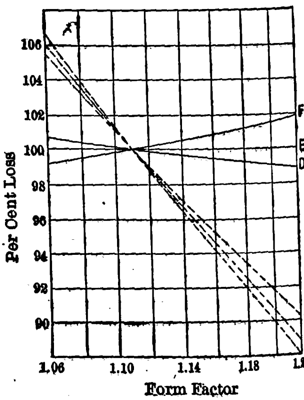

Fig. 13.

In making commercial tests on transformers it is frequently inconvenient to obtain a sine-wave voltage, and it is also equally inconvenient to obtain the form factor of the actual voltage available and the relative value of the eddy-current loss. Yet, for comparative purposes, the core-loss should be referred to a standard sine-wave form. The iron-loss voltmeter, devised by L. W. Chubb (*Trans. A.I.E.E., 1909, Vol. 28, p. 417*) is an instrument designed to read, when connected to a circuit in which the voltage has *any wave form whatever*, the value of the sine-wave voltage which would produce the same total loss as produced by the actual voltage. The meter is calibrated for one frequency only, usually 60 cycles per second. When such an instrument is connected across the transformer and the voltage adjusted until the instrument reads the rated voltage of the transformer, the core-loss read by a wattmeter connected in the usual manner will be the core-loss corresponding to a sine-wave voltage having an effective value equal to the voltage read by the iron-loss voltmeter, irrespective of what the reading of an ordinary voltmeter connected across the line may be.

Chubb's iron-loss voltmeter is essentially an ordinary wattmeter, the current coil of which is connected in series with a winding on a small laminated iron core, these two elements in series being connected directly across the line. The potential circuit of the wattmeter is also connected across the line to the same two terminals as the first or series circuit. The meter therefore has but two terminals. The deflection of the moving element of such a meter, when con-

nected across the supply mains, is proportional to the total power absorbed by the circuits and the iron core. Neglecting the small resistance loss in the series circuit, it is possible, by adjusting the resistance in the potential circuit and the number of turns on the iron ring, to make the equivalent eddy-current loss in the instrument (including the resistance loss in the potential circuit as an eddy-current loss, since it depends on the effective value of the voltage in the same way as the eddy-current loss in the sample) any desired proportion of the total loss. These adjustments are so made that at about 0.6 full-scale deflection the equivalent eddy-current loss on a pure sine-wave voltage at 60 cycles is 20 per cent of the total, this being the average proportion of the hysteresis loss to total loss in commercial 60-cycle transformers.

The instrument is then calibrated to read directly in volts by connecting it in parallel with an ordinary alternating-current voltmeter on a pure sine-wave voltage of the required frequency.

The voltage to be used for a core-loss test on any circuit, irrespective of wave form, is then read by means of this instrument instead of by an ordinary voltmeter. If the transformer under test has the same per cent eddy-current loss as the equivalent eddy-current loss in the iron-loss voltmeter, then the reading of an ordinary wattmeter connected to measure the core loss of the transformer in the ordinary way will be the loss on a sine-wave voltage having an effective value equal to the reading of the iron-loss voltmeter. If the percentage hysteresis loss is different from that of the iron-loss voltmeter, a slight error will be introduced. Curves D and F in Fig. 13 show the error when the eddy-current loss in the transformer is 14 per cent and 30 per cent respectively, instead of 20 per cent.

The voltage may be regulated through a considerable range by the use of a resistance or inductance, thus dispensing with the usual multi-tap transformer or field regulation of generator. The frequency need only approximate the normal values; the final core loss determined at the voltage indicated by the iron-loss voltmeter will be the same as would be obtained on a sine wave of normal frequency and voltage.

Adjustment of Form Factor. — Chubb also gives a method of obtaining a form factor of 1.11 from a wave of any shape. This is shown in Fig. 14. T is the transformer under test, W an ordinary wattmeter, V_1 the iron-loss volt-meter, V_2 an ordinary a-c. voltmeter, R a variable resistance, L a variable inductance, C an aluminum electrolytic condenser having a critical voltage less than that impressed across it. By varying L and R the readings of V_1 and V may be made to agree; under these conditions the form factor of the voltage across the transformer is 1.11. The wave however will not in general be a sine wave.

MAXIMA AND MINIMA. — (*See also Derivatives; Series, Mathematical.*) Let y be any function of a variable x, then y will be a maximum or minimum for any value of x which satisfies

$$\frac{dy}{dx} = 0 \qquad (1)$$

provided $\frac{d^2y}{dx^2}$ is not zero. If the second derivative $\frac{d^2y}{dx^2}$ is positive for this value of x, then the corresponding value of y is a minimum; if this second derivative is negative, the corresponding value of y is a maximum.

In case $\frac{d^2y}{dx^2}$ is also zero for the value of x which satisfies (1), the corresponding value of y is not a maximum or minimum unless $\frac{d^3y}{dx^3}$ is also zero and $\frac{d^4y}{dx^4}$ is not zero. When $\frac{d^3y}{dx^3} = 0$, y is a minimum if $\frac{d^4y}{dx^4}$ is positive and a maximum if $\frac{d^4y}{dx^4}$ is negative. In case $\frac{d^4y}{dx^4}$ is also zero, similar relations must hold for the fifth and sixth derivatives, etc.

Example. — Find the maximum and minimum values of

$$y = 2x^3 - 9x^2 + 12x - 3,$$

then

$$\frac{dy}{dx} = 6x^2 - 18x + 12 = 0,$$

$$\frac{d^2y}{dx^2} = 12x - 18,$$

whence y is maximum or minimum for $x^2 - 3x + 2 = 0$, that is, for $x = 2$, or $x = 1$. For $x = 2$, $\frac{d^2y}{dx^2}$ is positive; for $x = 1$, $\frac{d^2y}{dx^2}$ is negative; hence the maximum value of y is 2 and occurs for $x = 1$, while the minimum value of y is 1 and occurs for $x = 2$.

MECHANICS, PRINCIPLES OF. — (*See also Structures, Simple; Units and Conversion Factors.*) In this article are given the definitions of the more commonly-used mechanical quantities together with a statement of the quantitative laws in accord with which displacements and motion of matter (including deformations) take place. The interrelations of the various units employed for measuring any particular quantity are given in the article on *Units and Conversion Factors*.

DEFINITIONS. — The various terms relating to the displacement and motion of matter and to forces producing these displacements and motions are the following:

Scalar and Vector Quantities. — A mechanical quantity which is not directed in space, e.g., mass, energy, etc., is called a scalar quantity. A mechanical quantity which has a space direction as well as magnitude, e.g., velocity, force, etc., is called a vector quantity. A scalar quantity may be positive or negative, that is, has two "senses," but to specify a vector quantity like force it is necessary to specify not only its magnitude but its direction with respect to one or more fixed lines of reference or axes. Scalar quantities may be treated as ordinary algebraic quantities, and added and subtracted in the usual way. Vector quantities must be added and subtracted *vectorially*, as described in the article on *Vectors*.

Linear Displacement (l). — When a particle P moves from a point A to any other point B, the distance, measured along a straight line, from A to B is called the linear displacement of the point P.* Any unit of length may be used as a unit of displacement; see *Units and Conversion Factors*.

Angular Displacement (θ). — Let a particle P move from a point A to some other point B, and let OX be any arbitrarily-chosen line, or axis. Draw planes through A and OX and through B and OX. Then the angle between the planes AOX and BOX is called the angular displacement of P about OX. * Angular displacement may be measured in degrees, radians or turns; see *Angles* and *Units and Conversion Factors*.

Linear Velocity (v) **and Speed** (s). — The linear velocity or speed of a particle P is the rate of increase with time of the linear displacement of P, i.e.

$$v = \frac{dl}{dt} \qquad \text{or} \qquad s = \frac{dl}{dt}, \tag{1}$$

where dl is the linear displacement in time dt.
Any unit of length per any unit of time may be used as a unit of velocity or speed; see *Units and Conversion Factors*.

Angular Velocity or Speed (ω). — The angular velocity or speed of a particle about a given axis X is the rate of increase with time of its angular displacement about this axis, i.e,

$$\omega = \frac{d\theta}{dt}, \tag{2}$$

where $d\theta$ is the angular displacement in time dt. Any unit of angle per any unit of time may be used as a unit of angular speed; see *Units and Conversion Factors*.

* The positions of A and B (and of OX also in the case of angular displacement) must be referred to some system of coördinates; when the system of coördinates moves, the displacement as above defined is the displacement *relative to* this system of coördinates.

Linear Acceleration (a). — The linear acceleration of a particle P is the of increase with time of the linear velocity of P, i.e.,

$$a = \frac{dv}{dt} = \frac{d^2l}{dt^2}, \tag{3}$$

here dv is the increase of linear velocity in time dt. Any unit of velocity per any unit of time may be used as a unit of acceleration, *e.g.*, centimeters per second per second, miles per hour per hour, etc.; see *Units and Conversion Factors*.

Acceleration Due to Gravity (g). **Gravitational Acceleration Constant** (g_0). — At any given place on the earth a body falling freely in a vacuum has a constant linear acceleration, independent of its size, shape or material. This acceleration is called the acceleration due to gravity (g), and the particular value of this acceleration at 45 degrees latitude and sea level is called the gravitational acceleration constant (g_0). The value of g_0 as adopted by international agreement * is

$$g_0 = 980.665 \text{ cm. per sec. per sec.}$$
$$g_0 = 32.1739 \text{ ft. per sec. per sec.}$$

The value of g for any other location varies but slightly from this value, being at sea level approximately 0.3 per cent greater at the equator, 0.3 per cent less at the poles, and decreasing at the rate of about 0.01 per cent per 1000 feet increase in elevation. See *Landolt-Börnstein's Tables*.

Angular Acceleration (α). — The angular acceleration of a particle P about an axis X is the rate of increase with time of the angular velocity of P about X, i.e.,

$$\alpha = \frac{d\omega}{dt} = \frac{d^2\theta}{dt^2}, \tag{4}$$

where $d\omega$ is the increase in angular velocity in time dt. Any unit of angular velocity per any unit of time may be used as a unit of acceleration, e.g., degrees per second per second, turns per second per second, etc.; see *Units and Conversion Factors*.

Mass or Weight.* — Two bodies are said to have equal masses or weights,† irrespective of their volume, shape or chemical composition, if, when they are suspended simultaneously in a vacuum, one from each end of an equal-armed balance, there is no tipping of the beam of the balance from its original position. This criterion for the equality of two masses holds only in case the bodies and the balance are neither electrically charged nor magnetized, both bodies are supported at the same distance from the earth, and the equilibrium of the balance is not affected by the presence of any other bodies (except the earth) in the vicinity. This is an entirely arbitrary definition, but mass as thus defined is found to be a fundamental property of a body irrespective of its shape, physical state or relation to other bodies. The units of mass or weight and their interrelations are given in the article on *Units and Conversion Factors*.

Density (δ) **and Specific Gravity.** — The density of a uniform substance is defined as the mass of the substance per unit volume. When the substance

* *Troisième Conf. Gen. des Poids et Mes., 1901, p. 66.* See Note 5, p. 3 of this book.

† The term weight is also used for the force exerted by the earth on a portion of matter; in this sense weight is not independent of the relation of the given portion of matter to other bodies, and the term mass is therefore preferable when referring to quantity of matter, since it has not acquired a double meaning. However, engineers almost invariably use the word weight instead of mass for quantity of matter. See the article on *Units and Conversion Factors* for a further discussion of this point.

is not uniform, its density at any point is defined as the mass of an infinitesimally small volume taken about the point divided by this volume; i.e., calling dv the volume and dm the mass of this volume, the density is

$$\delta = \frac{dm}{dv}. \tag{5}$$

In the c.g.s. system the standard unit of density is the gram per cubic centimeter, but any other unit of mass per any unit of volume may be used in either the metric or English system; see *Units and Conversion Factors*. For values of the density of various materials see article on *Weights of Materials*.

The specific gravity of a substance is defined as the ratio of the weight of a given volume of that substance to the weight of an equal volume of water or air. Water is used as the standard of reference for solids and liquids, and air at 0° C. and 760 mm. mercury pressure as the standard of reference for gases. Strictly, the temperature of the water also should be specified, but this is not always done. The variation in the weight of a given volume of water with temperature is slight and for many purposes negligible. When 4° C. is taken as the standard water temperature the specific gravity of a substance is numerically equal to its density in grams per cubic centimeter to within 25 parts in 1,000,000, a difference which is very much less than the degree of precision of ordinary measurements of density.

Surface and Lineal Densities. — Density as defined above is the *volume* density of a body. It is sometimes convenient to use factors which represent the mass or weight of a substance (or other physical quantity) per unit of surface or per unit of length, e.g., the weight per square foot of a plate or the weight per foot of a wire.

Center of Mass, Center of Gravity, or Center of Inertia. — A body of mass M which has any size or shape may be considered as made up of a number of small particles of masses m_1, m_2, m_3, etc., such that $m_1 + m_2 + m_3 + \cdots = M$. These particles may be considered as small as desired, that is, each particle may be considered so small that it occupies but a point in space. Choose any three mutually perpendicular planes, fixed with respect to one another, and represent by x_1, y_1 and z_1 the perpendicular distances of the particle m_1 from these planes respectively, and by x_2, y_2 and z_2 the perpendicular distances of the particle m_2 from these three planes respectively, and so on for the other particles. Then the point whose distances from these three planes are respectively

$$\begin{aligned} X &= \frac{m_1x_1 + m_2x_2 + m_3x_3 + \cdots}{M} \\ Y &= \frac{m_1y_1 + m_2y_2 + m_3y_3 + \cdots}{M} \\ Z &= \frac{m_1z_1 + m_2z_2 + m_3z_3 + \cdots}{M} \end{aligned} \tag{6}$$

is defined as the center of mass, or center of gravity, or center of inertia, of the body. The name center of gravity arises from the fact that the vertical forces acting on all the various particles of a body, due to the pull of the earth, may be considered equivalent to a single force, equal to the sum of these individual forces, applied to the body at this point. The center of mass of a perfectly rigid body is a fixed point with respect to every point in the body; it may, however, lie either within or without the body.

Equations (6) may also be written in terms of the calculus, thus:

$$X = \int \frac{\delta x\, dv}{M}, \quad Y = \int \frac{\delta y\, dv}{M}, \quad Z = \int \frac{\delta z\, dv}{M}, \tag{6a}$$

where dv represents an elementary volume of the body at any point, x, y and z the distances of this point from the three planes of reference, δ the density of the body at this point, and M the total mass of the body. When the density is uniform throughout,

$$X = \int \frac{x\,dv}{V}, \quad Y = \int \frac{y\,dv}{V}, \quad Z = \int \frac{z\,dv}{V},$$

where V is the total volume of the body.

Centroid or Center of Gravity of a Plane Section. — This is defined as the point whose coördinates in the plane of the section are

$$X = \int \frac{x\,dA}{A} \quad \text{and} \quad Y = \int \frac{y\,dA}{A} \tag{6b}$$

referred to any two fixed mutually perpendicular lines in this plane, A being the total area of the section and dA any elementary area of the section. Physically, the center of gravity of a plane section may be defined as the center of gravity of a thin plate having the same shape as that of the section and of uniform thickness and specific gravity. See article on *Structures, Simple,* for the position of center of gravity for various plane sections.

Center of Gravity of Cylinders and Prisms. — The center of gravity of a cylinder or prism with parallel end surfaces and of *any* shaped cross-section, solid or hollow, is the centroid of that cross-section of the cylinder or prism which is halfway between the two ends, provided the cylinder has a uniform density throughout.

Moment of Inertia (I). — Consider any axis of reference X and any particle of mass m at a distance r from this axis; then the product mr^2 is called the moment of inertia of the particle m about the axis X. The moment of inertia of an extended body or system of bodies about any axis is

$$I = m_1r_1^2 + m_2r_2^2 + m_3r_3^2 + \ldots, \tag{7}$$

the summation including products mr^2 for all the particles of the body or system of bodies, r being the distance of the particle from the axis. This may also be written in the notation of the calculus as

$$I = \int r^2\,dm, \tag{7a}$$

where dm represents the mass of any particle and r is the distance from the axis. In case the body has a uniform density δ throughout this may also be written

$$I = \delta \int r^2\,dv, \tag{7b}$$

where dv represents an elementary volume of the body.

Units of Moment of Inertia of Bodies. — The moment of inertia of a body is of the nature of, or has the "dimensions" of, $(\text{length})^2 \times (\text{mass})$. When the mass is expressed in pounds and the distance r in feet then the moment of inertia may be said to be expressed in $(\text{foot})^2$-pounds, and similarly for any other units of mass and length. In applying the formulas below the same set of units must be used throughout. See *Units and Conversion Factors.*

Moment of Inertia of a Plane Section. — The moment of inertia of a plane section about any axis is defined by the relation

$$I = \int r^2\,dA, \tag{7c}$$

where dA represents any elementary area of this section and r the distance of this elementary area from the axis. When the axis is chosen *perpendicular* to the plane of the section *through its center of gravity* the moment of inertia about this axis is called the "polar" moment of inertia. Physically, the moment of inertia of a plane section about any axis may be defined as the moment of inertia about this same axis of a thin plate having the same shape as that of the section and having unit mass per unit of area.

The unit of moment of inertia of a plane surface has the dimensions of length to the fourth power.

Let X and Y be two mutually perpendicular axes in the plane of the section *passing through its center of gravity* and let Z be the axis through the center of gravity perpendicular to this plane and therefore also perpendicular to X and Y; let I_x and I_y be the moments of inertia of the plane section about X and Y respectively, and I_z be the polar moment of inertia of the section. Then

$$I_z = I_x + I_y. \tag{7d}$$

Values of I_x and I_y for various plane figures are given in the article on *Structures, Simple.*

Let X be any axis in the plane of a section, X_0 an axis through the center of gravity of the section parallel to X, x the distance between the two parallel axes X and X_0, I_0 the moment of inertia of the section about X_0, and A the area of the section. Then the moment of inertia of the section about X is

$$I_x = I_0 + x^2A. \tag{7e}$$

Principal Axes and Principal Moments of a Plane Section. — For every plane surface there are two rectangular axes passing through its center of gravity and lying in the surface, such that about one of these axes the moment of inertia is less, and about the other greater, than that about any other axis in the given surface. These two axes are called the *principal axes* and the moments the *principal moments of inertia.* If the plane figure has an axis of symmetry, this axis is one of the principal axes; e.g., a rectangle has two axes of symmetry, one parallel to each side, hence each of these axes is a principal axis. In the case of a circle any axis may be considered a principal axis. The principal axes for various sections are given in the article on *Structures, Simple.*

Moment of Inertia of Cylinders and Prisms. — Let the cylinder or prism be of any cross-section whatever, solid or hollow; let its density be δ, constant throughout; let the length of its own axis between the parallel end surfaces be l; and let I_s be the moment of inertia of the cross-section of the cylinder or prism about any axis X parallel to the length l; then the moment of inertia of the entire cylinder or prism about this axis X is

$$I_c = \delta l I_s. \tag{7f}$$

The density δ must be referred to a volume unit based upon the same unit of length as that in which the dimensions of the cylinder or prism are expressed. For example, if I_s is expressed in centimeters-to-the-fourth-power, δ must be expressed in mass per cubic centimeter, and l must be expressed in centimeters; if δ is in grams per cubic centimeter, then the moment of inertia is in (centimeter)^2-grams.

Radius of Gyration (ρ). — The radius of gyration of a body about any axis is defined by the relation

$$I = M\rho^2 \quad \text{or} \quad \rho = \sqrt{\frac{I}{M}}, \tag{8}$$

where M is the mass of the body and I its moment of inertia about the given axis. When the body has a uniform density throughout the radius of gyration may also be written

$$\rho = \sqrt{\frac{\int r^2 dv}{V}}, \tag{8a}$$

where V is the volume of the body. Radius of gyration is of the same nature as length and is therefore expressed in the same units as length.

Radius of Gyration of Plane Section. — The radius of gyration of a plane section about any axis is defined by the relation

$$\rho = \sqrt{\frac{\int r^2 dA}{A}}, \tag{8b}$$

where A is the total area of the section, dA an elementary area of this section and r the distance of dA from the axis. Values of ρ_x and ρ_y for various sections are given in the article on *Structures, Simple.*

From formula (7d) it follows that if ρ_x and ρ_y represent the radii of gyration of a plane section about two mutually perpendicular axes *passing through the center of gravity* of the section, then the radius of gyration ρ_z of this section about an axis through its center of gravity *perpendicular* to the plane of the section is

$$\rho_z = \sqrt{\rho_x^2 + \rho_y^2}. \tag{8c}$$

For example, for a circular section $\rho_x = \rho_y = \frac{d}{4}$, where d is the diameter of the section. Hence the polar radius of gyration about a perpendicular axis through the center of the circle is $\rho_z = \frac{\sqrt{2}}{4} d$.

From formula (7e) it also follows that if ρ_0 is the radius of gyration about any axis X_0, then the radius of gyration about a *parallel* axis X at a distance x from X_0 is

$$\rho_x = \sqrt{\rho_0^2 + x^2}. \tag{8d}$$

Radius of Gyration of Cylinders and Prisms. — The radius of gyration of a cylinder or prism about any axis X parallel to its own axis is the same as the radius of gyration about the axis X of any plane section of the cylinder or prism, provided the end surfaces are parallel and the density is uniform throughout. This relation holds for a prism or cylinder of any shape of cross-section, whether solid or hollow.

Linear Momentum (mv). — When the *center of mass* of a body of mass m is moving with a linear velocity v with respect to any point P, the product mv is called the linear momentum of the body with respect to this point. Units of linear momentum are of the same nature or dimensions as the units of power; see *Units and Conversion Factors.*

Experience shows that in any system of bodies composed of two bodies or groups of bodies A and B, any change in the linear momentum of the first body or group of bodies A with respect to the center of mass of the system is accompanied by an equal and opposite change in the linear momentum of the second body or group of bodies B with respect to the center of mass of the system, and vice versa. This fact of experience is known as the *Principle of the Conservation of Linear Momentum.*

Angular Momentum ($I\omega$). — When a body has a moment of inertia I about any axis X and is rotating about this axis with an angular velocity ω with respect to any point P, the product $I\omega$ is called the angular momentum of the body about this axis with respect to the given point. Units of angular momentum are of the same nature or dimensions as those of linear momentum and of power; see *Units and Conversion Factors*.

Experience shows that in any system of bodies composed of two bodies or groups of bodies A and B, any change in the angular momentum of the first body or group of bodies A about any axis X is accompanied by an equal and opposite change in the angular momentum of the second body or group of bodies B about this same axis, and vice versa. This fact of experience is known as the *Principle of the Conservation of Angular Momentum*.

Force (f). — In general terms a force is that which produces or tends to produce a change in the state of rest or motion of a body, or "a force is pull or a push." The nature of force is not thoroughly understood, but the effects of a force, e.g., change in motion, the extension or compression of a spring, etc., are readily measured. From the principle of the conservation of linear momentum stated above it follows that any change in the motion of a body or portion of a body A is always accompanied by a change in the motion of some other body or portion of the same or of some other body B. Hence the body A is said to exert a force on the body B, and vice versa.

In a system composed of but two bodies A and B, uninfluenced by the presence of any other bodies, the measure of the force produced on the body A by the body B may be taken as the rate of change with time of the linear momentum of A with respect to the center of mass of the system formed by A and B. The measure of the force produced on B by A is similarly defined. From the principle of the conservation of linear momentum it then follows that the force produced on A by B is equal and opposite to the force produced on B by A, or "action and reaction are equal and opposite."

Stated in a formula the above definition is that the mutual force between any two bodies A and B whose motion is uninfluenced by any other forces is

$$f = m_1a_1 = -m_2a_2, \tag{9}$$

where m_1 and m_2 are the masses of A and B respectively, and a_1 and a_2 are the accelerations of the centers of mass of A and B respectively with respect to the center of mass of the system formed by A and B together.

Force of Gravitation. — For example, consider the case of a mass m at any point above the earth. The earth exerts a force on m and m exerts an equal and opposite force on the earth, and if there are no other forces acting m will move toward the joint center of mass of the earth and the body m, and similarly the earth will move toward this same point. However, as the earth has a mass many times that of any body at or near its surface, the center of mass of the system formed by m and the earth is practically that of the earth itself, and the motion of the earth with respect to this point is inappreciable. Hence the force exerted by the earth on the mass m is, within the limits of error of observation,

$$f = mg, \tag{9a}$$

where g is the acceleration of the center of mass of m with respect to the center of the earth, or with respect to any point fixed with respect to the surface of the earth in the vertical line through the center of mass of m.

Units of Force. — The rational unit of force is that force which will give unit linear acceleration to unit mass; this unit of force is called the "absolute" unit of force. When the mass is expressed in grams and the acceleration in centimeters per second per second, the corresponding absolute unit

of force is called the "dyne;" when the mass is expressed in pounds and the acceleration in feet per second per second, the corresponding absolute unit of force is called the "poundal."

The relation expressed by equation (9a), however, suggests another unit of force which for many purposes is very convenient, and in fact is the unit ordinarily used by engineers. This unit, called the "gravitational" unit of force, is the force exerted by the earth on unit mass; since the value of this force in terms of the absolute unit varies with latitude and elevation, it is also necessary to specify a definite place of measurement of this unit force, or better a *definite* value of the acceleration g, which shall be used in evaluating this force in terms of the absolute unit. The value of g adopted by international agreement is $g = 980.665$ cm. per sec. per sec. $= 32.1739$ ft. per sec. per sec., which (see Note 5 at top of p. 3 of this book) is equal to the acceleration due to gravity at 45 degrees latitude and sea-level; see also above under *Acceleration.* Unfortunately the gravitational units of force are given the same names as the units of mass to which they refer; for example a force of 1 pound is the pull exerted by the earth on a mass of 1 pound at 45 degrees latitude and sea-level. This double use of names often leads to confusion unless one keeps clearly in mind the definitions of unit mass and unit force. See *Units and Conversion Factors.*

When the force acting on a body is expressed in absolute units, the relation between force, mass and linear acceleration is

$$f = ma \quad \text{absolute units.} \tag{9b}$$

When the force is expressed in gravitational units, the relation between force, mass and linear acceleration is

$$f = \frac{m}{g_0} \cdot a \quad \text{gravitational units,} \tag{9c}$$

where g_0 stands for the numerical factor 32.1739 when f is in pounds, m in pounds and a in feet per second per second; similarly when f is expressed in grams, m in grams and a in centimeters per second per second g_0 stands for 980.665.

Measurements of Force. — One seldom has to deal with a simple system of but two bodies, and consequently the above definitions of the measure of a force can seldom be applied to an actual measurement. The value of these definitions is that they fix the unit of force. Forces are measured by balancing the pull of an unknown force against a known force (e.g., gravity or the reacting force of a spring), the principles involved being deduced from the fundamental principle of the conservation of linear and angular momentum when applied to bodies in equilibrium; see the section on *Conditions for Equilibrium* below.

Weight and Force. — The word weight, as already noted, is used to designate both mass and force. A weight of 10 pounds, say, as ordinarily used in reference to "how much" of a substance, means that the piece of matter in question has a mass of 10 pounds. A weight of 10 pounds used in reference to the pull produced by the earth on a piece of matter means that this pull is a force of 10 pounds. From the above definitions it follows that, neglecting the slight variation with latitude and elevation, the *numerical* values of weight used in the two senses are equal, provided mass is expressed in absolute units and force in gravitational units, i.e., a mass of 10 pounds also weighs 10 pounds, but weighs 321.739 *poundals;* see above under *Units of Force.*

Point of Application and Line of Action of a Force. — Any particle or point of a body which is acted upon directly by some external force (e.g.,

a string attached to the body at this point) is said to be the point of application of this external force. A line drawn through this point in the direction of the force is called the line of action of the force. In general, whenever a solid body is acted upon by any number of external forces applied at various points the motion produced is the same as that which could be produced by *not more than two* single external forces. When the points of application of these two resultant forces coincide, then the actual motion produced is the same as that which would be produced by a *single* force acting at that point.

Impulse of a Force. — The impulse of a force is defined as the time integral of the force, i.e., if a force f is applied for a time t, then the impulse is $\int_0^t f\,dt$, account being taken of both the variation of the magnitude and direction of the force during the given time interval. The total change in the linear momentum of a body in any time t is equal to the impulse of the resultant force acting on it during this time. The conception of the impulse of a force is useful in dealing with suddenly applied forces which continue but a short time.

Concurrent and Coplanar Forces. — When the lines of action of all the external forces acting on a body meet in a point these forces are said to form a concurrent system of forces. When all the external forces acting on a body lie in the same plane they are said to form a coplanar system of forces.

Pressure (p). — The perpendicular component of the force per unit area exerted on any surface is called the pressure on that surface. Let df be the perpendicular or normal component of the force acting on an area dA, then the pressure at dA is

$$p = \frac{df}{dA}. \qquad (10)$$

The term pressure is sometimes used as a synonym for force and what is here defined as pressure is called the "intensity of pressure." The rational unit of pressure is force per unit area, e.g., dynes per sq. cm. or pounds per sq. in., but a number of other arbitrary units are employed, such as, one inch of water column, one millimeter of mercury column, one atmosphere, etc. A dyne per square inch is also a barie. A standard atmosphere is the pressure that will support a column of mercury 76 centimeters = 29.9212 inches high at 0° C. at a place where $g = 980.665$ centimeters per second per second; using Thiesen and Scheel's determination of the density of mercury at 0° C. as 13.59545 grams per cubic centimeter (*Zeitsch. f. Instrkde., 1898, Vol. 18, p. 138*) a standard atmosphere is equivalent to 14.6964 pounds per square inch. See *Units and Conversion Factors*.

Absolute Pressure. — The atmosphere exerts a pressure (ranging from about 29 to 30 inches of mercury, depending upon the weather conditions and elevation) upon every surface with which it is in contact. The total pressure on a surface including that applied by any artificial means and that of the atmosphere is called the absolute pressure on the surface.

Torque or Moment of a Force (T). — Consider any axis X and any force acting at a point P at a perpendicular distance r from this axis; let f be the *component* of this force perpendicular to the plane through X and P. Then the product

$$T = rf \qquad (11)$$

is called the moment of the force, or the torque due to this force, about the axis X. The distance r is called the "lever arm" or simply the "arm" of the force about this axis. Both absolute and gravitational units of torque are

used, the units being of the same nature or dimensions as the units of energy (see below), but the two words in the compound names of the energy units are usually reversed. For example the foot-pound is an energy unit but the corresponding unit of torque is called the pound-foot. The conversion factors, however, are identical; see *Units and Conversion Factors*. Torque is also frequently expressed as "torque at unit radius," e.g., a torque of so-many pounds at 1 foot radius is a common expression; a more exact expression for the measure of torque would be "force at unit radius."

Torques about the same axis can be added algebraically, and torques about several axes meeting in a point can be added vectorially.

Couples. — Two equal and opposite parallel forces which are not concurrent (i.e., do not act along the same line) are said to form a couple, and the strength of the couple is defined as the product of either force by the perpendicular distance between their lines of action. The torque produced by a couple about any axis perpendicular to the plane of the two forces is equal to the strength of the couple.

Torque and Angular Acceleration. — The relation between torque, moment of inertia and angular acceleration is the same as that between force, mass and linear acceleration, i.e.,

$$T = I\alpha, \qquad \text{absolute units,} \tag{12}$$

where T is the torque in absolute units, I the moment of inertia and α the angular acceleration, all about the same axis. When the torque is expressed in gravitational units the relation is

$$T = \frac{I}{g_0}\alpha, \qquad \text{gravitational units,} \tag{12a}$$

where g_0 is a number numerically equal to 32.1739 when T is expressed in pound-feet, I in (foot)^2-pounds and α in radians per second per second; similarly for the centimeter-gram-second units $g_0 = 980.665$.

Work and Energy. — When the point at which a force is applied to a body A moves* with respect to the agent producing the force, in such a manner that the force has a component in the direction of the displacement of its application point, the force is said to do work; the body B exerting the force on A is also said to do mechanical work on the body A. As a measure of the mechanical work dW done by the force f, when its point of application moves a distance dl with respect to the body producing the force, is taken the product of the displacement dl by the component of the force f in the direction of this displacement, i.e.,

$$dW = (f \cos\theta)\, dl, \tag{13}$$

where θ is the angle between the direction of the force and the direction of the displacement. For a finite displacement the mechanical work done is

$$W = \int_0^l f\, (\cos\theta)\, dl. \tag{13a}$$

When mechanical work is done on a body a change in the state of motion or in some other condition of the body is always produced. Like changes can also be produced by other means. For example, when two bodies are rubbed together rapidly, mechanical work is done on them by the agent which produces the force which moves one over the other against the opposing force due to friction. As a result, the temperature of the bodies is raised. The

* Either as a result of the motion of the body A as a whole or in consequence of the motion of that part of A to which the force is applied.

temperature of the two bodies may also be raised by placing them near or in contact with a hotter body, without there being any appreciable amount of *mechanical* work done. In general, any change produced in a body or system of bodies by any means whatever, which change can also be produced directly by doing mechanical work on that body or system, or indirectly by doing mechanical work on some other body or system, is said to be due to a transfer of "energy" *to* that body or system; or work * is said to be done on that body or system, irrespective of the means whereby the change is produced.

As a measure of the gain in energy corresponding to any change in a body or system of bodies is taken the amount of mechanical work which would have to be done by a mechanical force to produce this change and no other. For example, water can be heated by stirring it rapidly with a paddle driven by some external force; the total mechanical work done by this force can be expressed in terms of the value of the force, the number of revolutions of the paddle and the diameter of the pulley attached to the paddle, and the mass of the water and the resultant temperature rise can be measured. By making proper corrections for the work done against the various frictional forces other than the opposing force due to the stirring of the water itself and for the loss of energy by radiation, the amount of work required to raise the temperature of a pound of water, say, one degree Fahrenheit can be determined. By this means a very convenient secondary unit of energy can be expressed in terms of the unit of mechanical work, and the secondary unit can be used for expressing the amount of energy involved in various heat effects. See *Heat and Thermal Properties*.

Whenever a change takes place in a body or system of bodies which is the *reverse* of the change which can be produced in it by doing work *on* it, the body or system is said to *lose* energy, or energy is said to be transferred *from* it, or it is said *to do* work. As a measure of the amount of energy lost by the body or system when a given change takes place in it is taken the amount of work which would have to be done on it to restore it to its original condition.

Units of Work and Energy. — The fundamental unit of mechanical work in the c.g.s. system is the work done by a force of 1 dyne when its point of application is displaced (with respect to the agent producing the force) a distance of 1 centimeter in the direction of the force; this unit is called the "erg." The "joule" is equal to 10^7 ergs, by definition. The fundamental unit of mechanical work in the English gravitational system is the foot-pound, which is the work done by a force of 1 pound when its point of application is displaced a distance of 1 foot in the direction of the force; or 1 foot-pound is the work required to raise a mass of 1 pound a distance of 1 foot at a place where the acceleration due to gravity is 980.665 cm. per sec. per sec. or 32.1739 ft. per sec. per sec. Energy is expressed in the same units as mechanical work and in addition various heat units, such as the British thermal unit, the large and small calories, etc., are used; see *Heat and Thermal Properties*. For the relations among the various units see *Units and Conversion Factors*.

Principle of the Conservation of Energy. — Experience indicates that the amount of energy, as above defined, which can be transferred from a body or system of bodies to which no energy is added, is limited; i.e., the energy "possessed by" or "associated with" any body or system of bodies is *finite* in amount. As a rule, only a relatively small portion of the energy

* The word "work" is used by some writers to signify mechanical work only, but the term is a very convenient one to use in referring to the transfer of energy by other means as well, i.e., any change resulting in a transfer of energy to a body may be said to result from the doing of "work" on the body, whether the change is produced by mechanical, electrical or other means.

associated with a body or system can be transferred to another body or system. Experience also justifies the assumption that whenever one body or system of bodies *gains* energy, some other body or system *loses* an *exactly equal amount* of energy. In every instance where this assumption can be tested directly it is found to hold, and every deduction from it has been found to be in accord with experimental fact. Hence this assumption is accepted as a fundamental principle of nature.

Kinetic Energy. — Work is required to set a body in motion, for while its motion is changing it is accelerating and therefore a force must be exerted upon it. From the definitions of acceleration, force and work given above it follows immediately that the work required to change the *linear* velocity of a body from v_0 to v_1 is

$$W_t = \frac{1}{2} m (v_1^2 - v_0^2) \qquad \text{absolute units,}$$

or

$$W_t = \frac{1}{2} \frac{m}{g_0} (v_1^2 - v_0^2) \qquad \text{gravitational units,}$$

where m is the mass of the body and g_0 is the gravitational constant. Similarly, the work required to change the angular velocity of a rigid body about a given axis from ω_0 to ω_1 is

$$W_r = \frac{1}{2} I (\omega_1^2 - \omega_0^2) \qquad \text{absolute units,}$$

or

$$W_r = \frac{1}{2} \frac{I}{g_0} (\omega_1^2 - \omega_0^2) \qquad \text{gravitational units,}$$

where I is the moment of inertia of the body about this axis and g_0 the gravitational constant. The expression

$$\frac{1}{2} mv^2 \qquad \text{or} \qquad \frac{1}{2} \frac{m}{g_0} v^2 \tag{14}$$

is called the "kinetic energy of translation" of the body, and the expression

$$\frac{1}{2} I\omega^2 \qquad \text{or} \qquad \frac{1}{2} \frac{I}{g_0} \omega^2 \tag{14a}$$

is called the "kinetic energy of rotation" of the body, both referred to the point with respect to which the velocities are measured.

Total Kinetic Energy of a System of Bodies. — The total kinetic energy of a moving system of bodies is equal to (1) the kinetic energy of the entire system moving with a velocity equal to the velocity of the center of mass of the system plus (2) the sum of the kinetic energies, rotational and translational, of each constituent body of the system due to the relative motion of this constituent body with respect to the center of mass of the whole system. For example, the total kinetic energy of a railway car is

$$W = \frac{1}{2} Mv^2 + \frac{1}{2} \Sigma I\omega^2 \qquad \text{absolute units,} \tag{14b}$$

$$W = \frac{1}{2} \frac{M}{g_0} v^2 + \frac{1}{2 g_0} \Sigma I\omega^2 \qquad \text{gravitational units,} \tag{14c}$$

where M is the entire mass of the car with full equipment, I the moment of inertia, ω the angular velocity of any rotating part and the summation sign Σ indicates the sum of the products $I\omega^2$ for all the rotating parts. See also *Railways, Energy Requirements for*.

Potential Energy. — The energy possessed by a body in virtue of its position with respect to the earth is usually called potential energy. More generally the term potential energy is used to designate any form of energy other than kinetic energy. In absolute units the increase in the potential energy of a body when it is raised a vertical distance h is mgh; in gravitational units the increase in potential energy is mh.

Power. — By power is meant the time rate of doing work or the time rate of change of energy. Let dW be the work done in time dt, then the power is

$$P = \frac{dW}{dt}. \qquad (15)$$

The power produced by a force f or a torque T can also be expressed as

$$P = fv \qquad \text{or} \qquad P = T\omega, \qquad (15a)$$

where v is the linear velocity of the point of application of the force and ω is the angular velocity of the point of application of the torque. The rational unit of power is the unit of work done or of energy transferred per unit time, such as 1 erg per second, 1 joule per second, 1 foot-pound per second, 1 British thermal unit per second, and the like. 1 joule per second is called the watt, which is also equal to the power corresponding to 1 ampere and a potential difference of 1 volt (*see Units, Practical Electrical*). The horse-power (English and American) is defined* as the power corresponding to 550 foot-pounds per second or 33,000 foot-pounds per minute. The metric horse-power, also called cheval-vapeur, force de cheval, Pferde-kraft, is defined as 75 kilogram-meters per second. The boiler horse-power is defined in the article on *Boilers, Steam*. The interrelations of the various units of power are given in the article on *Units and Conversion Factors*.

CONDITIONS FOR EQUILIBRIUM. — A body or system of bodies is said to be in equilibrium with respect to any external body (e.g., the earth) when (1) there is no change in the motion of the center of mass of the system with respect to this external body and (2) when there is no change in the total angular momentum of the body or system about any axis fixed with respect to this external body. These two conditions require (1) that the resultant of all the external forces† acting on the body or system be zero and (2) that the resultant of all the moments of these external forces, or torques, about any axis acting on the body or system be zero. These two conditions are most conveniently expressed by choosing three mutually perpendicular axes fixed with reference to the body of reference (e.g., the earth) and resolving all the forces into components F_x, F_y and F_z parallel to these three axes and calculating the moments or torques T_x, T_y and T_z of each of these forces about these three axes; then, using the symbol Σ to indicate the algebraic summation of the individual x, y or z components,

$$\left.\begin{array}{ll} \Sigma F_x = 0 & \Sigma T_x = 0 \\ \Sigma F_y = 0 & \Sigma T_y = 0 \\ \Sigma F_z = 0 & \Sigma T_z = 0 \end{array}\right\} \qquad (16)$$

* The Bureau of Standards recommends the adoption of 746 watts as the definition of a horse-power. The older definition given above makes a horse-power 745.701 watts, using the standard value of g_0 given above, namely, 980.665 cm. per sec. per sec. and the legal values of the foot and the pound (*see Units and Conversion Factors*). As this older definition is the one generally employed by all classes of engineers, it seems preferable to the author to retain it. See *Circular No. 34 of the Bureau of Standards* and discussions in the various technical journals during 1912 and 1913.

† i.e., forces any one of which would, if acting alone, produce a motion of the body or system or of some part of it with respect to the reference body.

These two sets of conditions constitute the basis of the entire subject of statics. Certain elementary applications are given in the article on *Structures, Simple.*

Stability. — When a body or system of bodies is in equilibrium and the state is such that when the body or system is displaced slightly it returns of itself to its original condition, the equilibrium is said to be stable; if when displaced slightly the body or system moves farther from its original condition, the equilibrium is said to be unstable; if when displaced slightly it remains in that condition, the equilibrium is said to be stable. The condition for stability may be expressed in a number of ways, viz.: (1) when the potential energy of the system with respect to the body of reference (e.g., the earth) is a minimum the equilibrium is stable; (2) when the forces acting are all gravitational the equilibrium is stable when the center of mass is in the lowest possible position; or (3) when the body or system rests on a number of points, the equilibrium is stable only when the resultant of all the forces acting on the body including its own weight, but excluding the supporting forces, cuts the smallest polygon which can be drawn including all the points of support.

MOTION OF A PARTICLE. — By a particle of matter is meant a portion of matter so small that it may be considered as occupying but a point in space. Let m be the mass of the particle, v its linear velocity at any instant with respect to any arbitrarily chosen set of axes of reference, dv the increase in its velocity in time dt (including both change in direction as well as in magnitude), and let F be the resultant of all the external forces, in absolute units,* acting on the particle. Then the motion of the particle is completely specified by the equation

$$F = m\frac{dv}{dt},$$

where dv is taken to include the change in *direction* as well as the magnitude of the velocity. To take into account the variation of the direction of v as well as the variation in its magnitude, the resultant force F and the velocities may be resolved into components along the three axes, in which case this equation breaks up into the three equations

$$F_x = m\frac{dv_x}{dt}, \qquad F_y = m\frac{dv_y}{dt}, \qquad F_z = m\frac{dv_z}{dt}.$$

Since the velocity along any axis is equal to the time rate of displacement along that axis, $v_x = \frac{dx}{dt}$, $v_y = \frac{dy}{dt}$, and $v_z = \frac{dz}{dt}$, whence these equations may also be written

$$\frac{d^2x}{dt^2} = \frac{F_x}{m}, \qquad \frac{d^2y}{dt^2} = \frac{F_y}{m}, \qquad \frac{d^2z}{dt^2} = \frac{F_z}{m}. \qquad (17)$$

Hence when the forces can be expressed in terms of the coördinates of the point which the particle occupies at each instant, the displacements and velocities can be determined by solving these equations. Note that $\frac{F_x}{m}$, $\frac{F_y}{m}$ and $\frac{F_z}{m}$ are the accelerations a_x, a_y and a_z along the three axes.

Rectilinear Motion. — The simplest case is that of a particle acted upon by a force F which remains constant in direction. One of the axes, say the

* When F is expressed in gravitational units replace m by $\frac{m}{g_0}$, where g_0 is the gravitational constant.

X axis, may be taken parallel to the line of action of the force, in which case equations (17) reduce to the single equation

$$\frac{d^2x}{dt^2} = \frac{F}{m}, \tag{17a}$$

and there is no acceleration along either of the other axes; i.e., the particle moves along the line of action of the force. If the force is also constant in magnitude, $\frac{F}{m} = a$, a constant. In this case the solution of (17a) is (*see Equations*):

$$\left.\begin{aligned} x - x_0 &= \frac{1}{2} a (t - t_0)^2 + v_0 (t - t_0), \\ v - v_0 &= a (t - t_0), \end{aligned}\right\} \tag{17b}$$

where $t - t_0$ represents any interval of time, $x - x_0$ the displacement of the particle during this interval and $v - v_0$ the change in velocity of the particle during this interval. The displacement $x - x_0$ may also be written

$$x - x_0 = \frac{v^2 - v_0^2}{2a}. \tag{17c}$$

Curvilinear Motion; Motion in a Circle. — Consider the special case of a particle moving in a circle of radius r with a constant tangential or peripheral velocity v. Choose the Z axis perpendicular to the plane of the circle. Let θ be the angle (measured counter-clockwise) which a line drawn from the center of the circle to the particle makes at any instant with the X axis, then $(90 - \theta)$ is the angle which this line makes with the Y axis at this instant. At any instant, then,

$$v_x = -v \sin\theta \qquad \text{and} \qquad v_y = v \cos\theta$$

and these components are not constant since θ changes with time. The corresponding accelerations along the two axes are

$$a_x = -v \cos\theta \frac{d\theta}{dt} \qquad \text{and} \qquad a_y = -v \sin\theta \frac{d\theta}{dt}.$$

both of which components are *toward* the center of the circle. But $\frac{d\theta}{dt}$ is the angular velocity of the particle about the Z axis, and this is equal to the peripheral velocity divided by the radius, or $\frac{d\theta}{dt} = \frac{v}{r}$. Whence

$$a_x = -\frac{v^2}{r} \cos\theta \qquad \text{and} \qquad a_y = -\frac{v^2}{r} \sin\theta,$$

and therefore the resultant acceleration has the numerical value

$$a = \sqrt{a_x^2 + a_y^2} = \frac{v^2}{r} \tag{17d}$$

and is *toward* the center of the circle. Hence to cause a particle to rotate in a circle a force equal to $\frac{mv^2}{r}$ must be applied to it in the direction *toward* the center, and the particle in turn pulls away from the center with an equal and opposite force which produces a tension outward along the radius in whatever (e.g., a string) holds the particle to the center. The tendency of the particle to pull outward from the center is called the centrifugal force, and its value

is $\frac{mv^2}{r}$; the equal inward pull required to make the particle move in the circular orbit is called the centripetal force.

Simple Harmonic Motion. — (*See also Wave Analysis.*) By simple harmonic motion is meant a motion such that the acceleration of the moving particle or point at each instant is proportional to, but in the opposite direction from, the displacement. Such motion may be either rectilinear or a rotation about a fixed axis. Rectilinear simple harmonic motion may also be defined, see Fig. 1, as the motion of the projection P on a given diameter YY', of a point Q which moves with a constant angular velocity ω around a circle of radius A. The motion of the bob of a simple pendulum, the position of the end of a piston rod, etc., are examples of simple rectilinear harmonic motion (very nearly).

Referring to the circle diagram in Fig. 1, P_0 represents the projection of the moving point Q at time $t = 0$. The angle made by OQ at any instant with

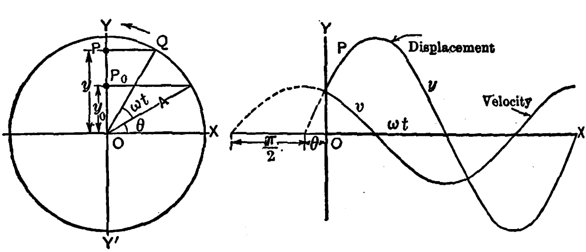

Fig. 1. Harmonic Motion

OX is then $(\omega t + \theta)$. The linear velocity of Q is $A\omega$, and the *component* of this velocity at any instant *along* OY, i.e., the velocity of P, is

$$v = \frac{dy}{dt} = A\omega \cos(\omega t + \theta). \tag{18}$$

Whence the displacement y of P from O is, by integration,

$$y = A \sin(\omega t + \theta), \tag{18a}$$

and the acceleration along OY is, by differentiation,

$$a = \frac{d^2y}{dt^2} = -\omega^2 A \sin(\omega t + \theta), \tag{18b}$$

whence $a = -\omega^2 y$, which agrees with the first definition of harmonic motion.

Period and Frequency. — The period of any kind of an oscillation is defined as the time (usually in seconds) taken for the oscillating point to pass through a complete cycle of values back again to the starting point. The frequency is the number of complete cycles per unit time (usually per second). In the case of a harmonic oscillation the period is

$$T = \frac{2\pi}{\omega} \tag{18c}$$

and the frequency is

$$f = \frac{\omega}{2\pi}. \tag{18d}$$

Amplitude.—The "sine curves" to the right of the circle diagram show the variation with time of the displacement and the velocity (along OY) of the projected point P. Displacement and velocity are plotted along the Y axis and ωt, which is proportional to time, is plotted along the X axis. These curves bear a definite relation to each other and to the "origin" of time, i.e., to the point O. The maximum ordinate of each curve is called the "amplitude" of the curve. The amplitude of the displacement curve is A, the radius of the circle; the amplitude of the velocity curve is ωA.

Phase.—The distance expressed in angular measure, from the origin to the point at which the curve first crosses the X axis in the *rising* direction is called the "phase angle" of the curve. The phase angle is taken positive when it is measured to the *left* from the origin, and negative when measured to the right.* The phase angle of the displacement curve is θ, and the phase angle of the velocity curve in the above case is $\frac{\pi}{2}+\theta$.

Difference in Phase.—The difference in the phase angles of two sine curves of the same frequency is called the "difference in phase" between the two curves; the difference in phase between the displacement curve and the velocity curve in the above case is $\frac{\pi}{2}$ radians or 90 degrees. The curve which has the larger (algebraically) phase angle is said to "lead" the other curve, and the one with smaller (algebraically) phase angle is said to "lag behind" the other one. In the above example the velocity curve leads the displacement curve. Note that the curve to the left is the leading curve.

ROTATION OF A SOLID BODY.—When a solid body moves in such a manner that one straight line through the body remains fixed with respect to any given set of axes of reference, its motion is called simple rotation with respect to these axes. For such motion the external forces must be equivalent to two equal and opposite forces which have a moment only about the axis of rotation. Let T be the value of this moment or torque, I the moment of inertia of the body about this axis and $d\omega$ the increase in the angular velocity about this axis in time dt (the same for each point of the body), then the motion is completely specified by the equation

$$\left.\begin{aligned} &T = I\frac{d\omega}{dt} && \text{(for } T \text{ in absolute units)} \\ \text{or}\quad &T = \frac{I}{g_0}\frac{d\omega}{dt} && \text{(for } T \text{ in gravitational units).} \end{aligned}\right\} \tag{19}$$

For constant torque and therefore constant angular acceleration, i.e., for $\frac{d\omega}{dt}=\alpha=$ constant, the change in angular velocity in the interval of time (t_2-t_1) is

$$\omega_2-\omega_1=\alpha\,(t_2-t_1), \tag{19a}$$

and the angle turned through in the interval (t_2-t_1) is

$$\theta_2-\theta_1=\frac{1}{2}\,(\omega_2+\omega_1)\,(t_2-t_1)=\frac{\omega_2^2-\omega_1^2}{2\,\alpha}. \tag{19b}$$

THREE-DIMENSIONAL MOTION.—The motion of a solid body may in the most general case be expressed in terms of a translation of its center and a rotation of the body around an axis through its center of mass. The motion

* The opposite convention is used by some writers, in which case the equation for the sine curve is $y=A\sin(\omega t-\theta)$.

of the center of mass produced by any number of external forces is the same as would be produced by a single force, equal to the vector sum of the actual forces, acting on a single particle occupying the position of the center of mass in the actual body and having a mass equal to the entire mass of this body. The rotation can be determined by considering the center of mass as fixed and the actual forces then applied. That is, the translation of the center of mass and the rotation about the axis through it can be considered independently of each other; the actual motion is then the resultant of these two types of motion. See *American Civil Engineers' Pocket Book* for a brief treatment of this subject.

MENSURATION. — (*See also Angles; Equations; Trigonometry.*) The term mensuration is used in this article to include the relations between the areas and volumes of geometric figures and their linear dimensions.

Triangle. —

$$\text{Area} = \tfrac{1}{2}\,(\text{base}) \times (\text{perpendicular height})$$
$$= \sqrt{s\,(s-a)\,(s-b)\,(s-c)},$$

where a, b and c are the lengths of the three sides respectively, and $s = \tfrac{1}{2}(a+b+c)$.

Trapezoid. —

$$\text{Area} = \left(\frac{a+b}{2}\right) d,$$

where a and b are the lengths of the parallel sides respectively, and d their distance apart.

Parallelogram. —

$$\text{Area} = (\text{base}) \times (\text{perpendicular height}).$$

Parabola. —

$$\text{Area} = \tfrac{2}{3}\,(\text{area of circumscribing triangle}).$$

Cycloid. —

$$\text{Area} = \tfrac{3}{4}\pi \times (\text{altitude})^2,$$

the altitude being the diameter of the rolling circle.

Circle. —

$$\text{Circumference} = 2\pi r = \pi d,$$

$$\text{Area} = \pi r^2 = \frac{\pi}{4} d^2,$$

where r is the radius and d the diameter.

$$\text{Area of segment} = \frac{r^2}{2}\,(\theta - \sin\theta),$$

where θ is the angle in radians (*see Angles*) subtended by the arc of the segment. If n is the height of the segment, measured along the radius perpendicular to the chord,

$$\text{Area of segment} = \pi r^2 M - A\,(r-n),$$

where

$$A = \sqrt{n\,(2r-n)} \quad \text{and} \quad M = \frac{1}{180} \sin^{-1}\left(\frac{A}{r}\right).$$

Ellipse. —

$$\text{Area} = \pi ab,$$

where a and b are the principal semi-axes.

Prism with Parallel Sides and Parallel Ends. —

$$\text{Volume} = (\text{area of end}) \times (\text{Perpendicular Distance between Ends}).$$

Right Circular Cylinder. —

$$\text{Volume} = \frac{\pi}{4} d^2 l,$$

where d is the diameter, and l the length.

$$\text{Total surface of right cylinder} = \pi d\,(l + \tfrac{1}{2} d).$$

Right Circular Cone. —

$$\text{Volume} = \tfrac{1}{3}\,(\text{area of base}) \times (\text{height}),$$
$$= \tfrac{1}{3}\,(\text{volume of circumscribing cylinder}),$$

where r is the radius of base and h the height of the cone.

$$\text{Area of curved surface of a right circular cone} = \pi r\sqrt{h^2 + r^2}.$$

Right Pyramid. —

$$\text{Volume} = \tfrac{1}{3}\,(\text{area of base}) \times (\text{height}),$$
$$\text{Volume of frustum of pyramid} = \tfrac{1}{3}\,(\text{height})\,(A + a + \sqrt{aA}),$$

where A and a are the areas of the ends respectively.

Sphere. —

$$r = \text{radius},$$
$$\text{Area of surface} = 4\pi r^2$$
$$= \tfrac{2}{3}\,(\text{total area of circumscribing cylinder}).$$

Area of the surface of a zone of a sphere = area of zone of the same height as this zone projected on to a cylinder.

$$\text{Volume} = \tfrac{4}{3}\pi r^3$$
$$= \tfrac{2}{3}\,(\text{volume of circumscribing cylinder}).$$

Volume of a frustum of a sphere $= \pi r^2 (k \mp h) - \frac{\pi}{3}(k^3 \mp h^3)$, where k is the distance of its outer face from center and h the distance of its inner face from the center, the negative signs in the brackets to be used if both faces are on the same side of the center and the positive signs if on opposite sides of the center.

Ellipsoid. —

$$\text{Volume} = \tfrac{4}{3}\pi abc,$$

where a, b and c are the three principal semi-axes respectively.

Paraboloid. —

Volume of a paraboloid of revolution equals one half that of the circumscribing cylinder.

[W. A. Del Mar.]

MOTOR-CONVERTERS. — (*See also Converters, Synchronous; Motors, Induction; Standardization Rules.*) A motor-converter is a combination of an induction motor and synchronous converter, with the secondary of the motor and the armature of the converter mounted upon the same shaft and connected together electrically without slip rings. The induction motor receives all the a-c. power, transforms a part of it into mechanical power delivered to the shaft, and also acts as a transformer delivering the rest of the power in electrical form at a lower frequency from its secondary to the armature of the converter. It operates like two induction motors in "concatenation" or "cascade." The object is to obtain the steadiness of a 30-cycle converter on a 60-cycle circuit.

The speed of a motor converter depends upon the supply frequency and varies inversely as the sum of the number of poles in both machines. Thus if a combination of a 6-pole motor and 6-pole converter be operated from a 60-cycle circuit the speed of the armature will be 600 r.p.m. The primary of the induction motor will operate at 60 cycles but the secondary will supply the armature of the converter with 30 cycles. Thus the converter may be built with the good design constants of a 30-cycle machine.

This combination is larger than a converter but smaller than a motor-generator set and its efficiency is lower than that of a converter. It is used somewhat in Europe but not much in the United States.

[W. I. Slichter.]

MOTOR-GENERATORS. — (*See also Converters, Synchronous; Generators; Motors; Standardization Rules.*) A motor-generator set is a combination of a motor and a generator having separate fields and armatures but mounted on the same shaft with common base and bearings. Combinations of various types of motors and generators are used; some of the more important combinations and their applications are described below.

Direct-current Motor Driving Direct-current Generator. — These sets are used when it is desired to convert low-voltage direct current into high voltage direct current, or vice versa; they are used in preference to a dynamotor (q.v.) when good regulation is desired in the secondary circuit.

Direct-current Motor Driving Alternating-current Generator. — These sets are used for converting direct into alternating current. See also the section on *Inverted Synchronous Converters* in the article on *Converters, Synchronous.*

Induction Motor Driving Direct-current Generator. — The induction motor may be wound for potentials as high as 13,000 volts and the transformation from alternating current at this voltage to direct current may be made without the use of transformers. Since the induction motor has a decreasing speed with increasing load the direct-current generator must be compounded to give good regulation; with proper compounding excellent regulation may be obtained. The induction-motor-generator set is sometimes used in preference to a synchronous converter when the service requires specially good regulation. However, the efficiency of such a set (about 85 per cent at rated load) is less than that of a synchronous converter, even if no transformers are required by the motor-generator set. The motor-generator set also occupies from 50 per cent to 80 per cent more floor space, weighs from 30 per cent to 50 per cent more, and costs from 25 per cent to 50 per cent more than a synchronous converter, in spite of the fact that they are designed to operate at the highest practicable speeds.

Costs and Speeds of Induction-motor-generator Sets. — Very roughly the prices and suitable speeds of induction-motor-generator sets are as follows:

Kw. capacity	R.p.m.	Cost per kw.
200	750	$23
500	500	16
1000	300	12.5

Synchronous Motor Driving Direct-current Generator. — This combination is preferable in many instances to the preceding, because it operates at constant speed and because the field of the synchronous motor may be adjusted to make use of line compounding or to compensate for low power factor in other apparatus on the circuit (*see Motors, Synchronous*). Provision must be made for the direct-current excitation for the synchronous motor. If the direct-current generator is wound for too high a potential a special exciter must be provided. Since there is no load on the set at starting the synchronous motor may be started in the usual manner.

Induction Motor Driving Alternating-current Generator. — An induction motor direct-connected to an alternating-current generator is frequently used to supply alternating current for special purposes at a frequency different from that of the main power station. Thus in power stations such a motor generator

set would be used to transform the 25-cycle power of the main generators to 60-cycle power for lighting circuits. This combination has the disadvantage of decreasing speed, and therefore decreasing frequency, with increasing load. In order that two such sets shall operate in parallel and divide the load properly the resistance of the secondary of both motors must be carefully chosen so that the motors have the same slip at full load. Other types of frequency changers are described below.

Synchronous Motor Driving Synchronous Generator; Frequency Changers.—The constant speed characteristic of a synchronous motor makes it particularly suited as the driving motor of a frequency changer. The generator of the set may be either an ordinary (i.e., synchronous) alternating-current generator or a reversed induction motor; the latter type is described in the next section.

In order that a synchronous-motor-synchronous-generator set may operate properly in parallel with other synchronous apparatus on the two systems to which the motor and generator are respectively connected, the number of poles of both motor and generator and the speed must be carefully chosen. Thus, to change from 25 to 60 cycles per second, the highest speed which allows an exact transformation of frequency is 300 rev. per min., and this requires 10 poles on the 25-cycle machine and 24 poles on the 60-cycle machine. In order to build less expensive sets, it is frequently the custom to use a speed of 750 rev. per min. with a 4-pole machine on the 25-cycle circuit and a 10-pole machine which will give 62.5 cycles for the other circuit. All the other machines on the latter circuit must then also operate at 62.5 cycles. Other combinations of poles and speeds for various combinations of frequency can be readily calculated by means of the usual relation between poles, speed and frequency; see *Generators, Alternating-Current*. Each motor-generator set must be provided with direct current for its field excitation, either from a direct-connected exciter or from a special exciter circuit.

Division of Load on Frequency Changers.—The parallel operation of sets of this character involves certain complicated considerations. In the first place the division of the load depends not only upon the voltage regulation of the two machines constituting a set, but upon the mechanical position of the armature on the shaft. Two machines built apparently the same may not divide the load equally because of inaccuracy in the placing of the keyway, etc. To avoid this trouble it is customary to mount one of the stationary members of one of the machines movable in a cradle so that the angular phase position of this member (usually the armature) with respect to the rotating member (usually the field) may be adjusted. The two sets to be operated in parallel are loaded, and the stationary armature of one machine is rotated in the cradle until the load between the two machines divides properly. This adjustment may also be used for testing, when it is desired to load the two machines one on the other without an external load by adjusting this "phase-angle" so that one machine operates as a generator when the other operates as a motor.

Synchronizing Frequency Changers.—The synchronizing of such machines is difficult, and several very complicated conditions must be satisfied. The theory is quite involved and is discussed at length in a paper by J. B. Taylor on *Parallel Operation*, *Trans.* A.I.E.E., Vol. 25, p. 113. The essential requirement is that it is necessary to synchronize not only the motor with its supply circuit but the generator with the secondary circuit. Thus when the motor has been synchronized properly it may be found that the generator instead of being in phase is 180 degrees out of phase with the secondary circuit. To bring the generator into phase it is necessary to cause it to "slip" one or

more poles; this can be done by reversing the field of the motor one or more times, depending upon the number of poles on the generator and motor. The necessity of more than one reversal is due to the fact that with a large number of poles on both motor and generator there are only a few combinations in which the poles of the motor and the generator of one set match up with the poles of motor and generator of another set.

In practice this difficulty is overcome by the use of a special synchronism indicator (*see Synchronizers*) having two hands appearing on the same dial. One hand shows the phase relation of each member of the set with its proper circuit. It is necessary to synchronize the set when both hands are not only stationary but point to the zero position. If only the motor were synchronized it would be found that both hands were stationary, but the motor hand would point to zero and the generator hand to some other position.

Induction-type Frequency Changers. — When the stator of an induction motor is excited from a supply circuit having a frequency of f_1 cycles per second and the rotor of this motor is driven by another motor in the *opposite* direction to that in which it would rotate due to the currents in its stator winding, the frequency of the current induced in the rotor winding is

$$f_2 = \frac{N_0 + N}{N_0} \cdot f_1,$$

where N_0 = synchronous speed of the motor and N = actual speed at which its rotor is driven. This combination of two motors (the driven motor really acts also as a generator) may therefore be used as a frequency changer.

Neglecting the losses in the driven motor, the electrical input into its stator is

$$\frac{f_1}{f_2} \times (\text{output of set at frequency } f_2)$$

and the mechanical output of the driving motor is

$$\frac{f_2 - f_1}{f_2} \times (\text{output of set at frequency } f_2).$$

While this combination is less expensive than the usual motor-generator set, it has the disadvantage of poor regulation, as every change in the potential of the supply circuit is transmitted to the receiving circuit; it is therefore but seldom used.

SPECIFICATION FOR MOTOR-GENERATORS.* — The following memoranda are intended to assist in writing specifications. See also articles on *Specifications; Motors;* and *Generators.*

General description and use of machine. Motor: see specifications in articles on *Motors.* Generator: see specifications in articles on *Generators.* Whether or not motor and generator are to be on common bed-plate. Exciter for generator field. Limiting over-all dimensions.

MOTORS, ALTERNATING-CURRENT COMMUTATOR. — (*See also Motors, Direct-current; Motors, Polyphase-induction; Motors, Single-phase Induction; Standardization Rules.*) There are several different types of alternating-current commutator motors designed to operate on single-phase circuits, but they differ chiefly in the electrical connections employed. They may be divided into two general classes, series motors and repulsion motors. While these motors differ in their connections and in slight details in their characteristics, they all have the general characteristics of the d-c. series motor, that is, increasing torque with decreasing speed and a high efficiency over a considerable range of speed. Alternating-current commutator motors with shunt motor characteristics are also used to a limited extent abroad.

GENERAL CHARACTERISTICS. — The torque of any a-c. commutator motor is constant in direction, but pulsating in value, and its average value

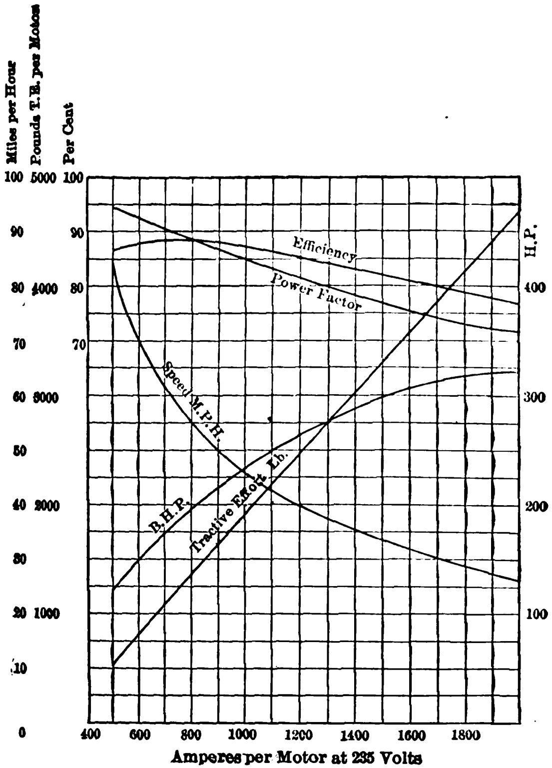

Fig. 1. Characteristic Curves of 1 Motor of the Single-phase Locomotives of the N. Y., N. H. & H. R. R. (St. Ry. Jour., Apr. 1906.)

is proportional to the product of the effective value of the flux and the effective value of the armature current. The direction of the torque may be changed

by changing the direction of the current in the field with respect to the armature, or vice versa. The power factor increases with increase of the speed and therefore decreases with increase of load. The efficiency, while not as good as that of a d-c. motor of the same rating is, however, fairly high. The motors have in addition to the losses common to d-c. motors a core-loss in the field, increased core-loss in the armature, increased commutation loss and increased RI^2 loss in special windings. In Fig. 1 are given the characteristic curves of the a-c. compensated series motors used on the single-phase locomotives of the New York, New Haven & Hartford Railroad.

APPLICATIONS. — The most general application of a-c. commutator motors in large sizes is in railway and hoisting work; see *Railways, Electric*, and *Hoists, Electric*. The same principles of operation are made use of in the devices for starting single-phase induction motors (*see Motors, Single-phase Induction*), the motor being brought up to speed as an a-c. commutator motor and then by a change of connections made to operate as a single-phase induction motor.

DESIGN. — The salient features in the design of the various types of a-c. commutator motors are described briefly below.

Straight A-C. Series Motor. — Since the torque of an ordinary d-c. series motor does not change in direction when the current through both the field and the armature reverses simultaneously, any d-c. series motor will develop a uni-directional torque when connected across a-c. mains. However, when an ordinary d-c. series motor is thus used the power factor of the load taken by it is very low, there is a large eddy-current loss in the field structure, and violent sparking occurs at the commutator. To make a series motor practicable for a-c. service, the field structure must be laminated in order to avoid eddy currents and the field coils must have only a few turns to avoid too great self-inductance, and the consequent low power factor. The greater tendency to spark in the case of the a-c. series motor is due to the *alternating* field flux which interlinks the coils short-circuited by the brushes, thus inducing in these coils a relatively large e.m.f. not present when the motor is operating on a d-c. circuit. This difficulty can be avoided to a certain extent by designing the motor for a small field flux and with but a few turns in series in each armature coil. In general, therefore, single-phase commutator motors are built for low voltages, such as 200, with one turn per coil, multiple-wound armatures and with the armature ampere turns per pole about four times the field ampere turns per pole. The effect of the armature ampere turns can be neutralized by a "compensating" winding described below. The field flux is practically limited to that value which will give 4 volts per turn in the short-circuited armature coil, as this is about the limit that may be commutated with carbon brushes.

Resistance Leads. — As an additional means of preventing sparking, high-resistance leads are frequently used between the commutator segments and the armature coils. These leads are made of a high-resistance metal strip bent back and forth several times, and imbedded in the armature slots along with the armature conductors proper. On account of the dissipation of heat in these leads a lower current density must be used in the armature conductors proper than is used in the case of d-c. motors. The arrangement of the leads is such that the main or useful current passes through two high-resistance leads in multiple as it enters the armature, while the undesirable short-circuited current passes through two high-resistance leads in series. It should be noted, however, that at any instant there is current only in those leads connected to coils which are being short-circuited at this instant.

Compensating Winding. — To obviate the high armature reaction in an a-c. series motor and at the same time to improve the power factor, a "compensating" winding is usually employed. This consists of a distributed winding imbedded in slots in the pole faces and connected usually in series (Fig. 2) with the main field winding and armature in such a manner that the current through it sets up a magnetomotive force which practically neutralizes the effect of the armature ampere turns. When the compensating winding is connected in series with the field and armature, as shown in Fig. 2, the motor is said to be "conductively compensated." An "inductively compensated" motor has this winding short-circuited upon itself and the current in it is induced from the armature by transformer action. Inductive compensation is not operative on d-c. circuits, but is as satisfactory as conductive compensation for a-c. operation.

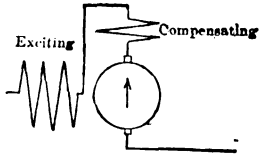

Fig. 2. Compensated Series Motor

Thomson Repulsion Motor. — This motor has a stationary structure or field with a completely distributed winding, which may be wound for any voltage. In this is placed a low-voltage armature designed with all the refinements necessary for single-phase commutator work. The brushes bearing on this commutator are short-circuited upon themselves and are so placed that the line connecting the positive and negative brushes makes an angle α with the neutral axis of the field. The field turns lying within the angle $(90 - \alpha)$ induce a current in the armature winding by transformer action and the field turns lying within the angle α constitute the "exciting" turns and set up the necessary flux to produce the driving force. The arrangement is equivalent to the circuits shown in Fig. 3, although actually there is but a single field winding. This motor then acts exactly like the combination of a transformer and a series motor in one structure. It may be reversed by changing the position of the brushes or by shifting the points of connection of the external circuit to the field or stator winding. This motor operates particularly well near synchronous speed as then it has practically a rotating magnetic field and no excessive commutation difficulties, but at starting and at low speeds the commutation is not as good as that of the compensated series type.

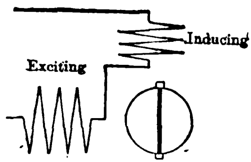

Fig. 3. Thomson Repulsion Motor

Winter-Eichberg Repulsion Motor. — In this motor the short-circuited brushes B_1 are set in the neutral axis of the field due to the stator winding, and an extra set of brushes is set halfway between the main brushes, see Fig 4. Through the latter set of brushes B_2 is sent either the entire main current or a certain portion of it; in the latter case a transformer T connected as shown is required. The main component of the armature current is induced from the stator winding by transformer action; the component entering the rotor through the brushes B_2 serves as the exciting current, setting up the necessary flux to produce the driving force. In a sense, then, the rotor serves both as the armature and the field of the motor, the stator winding acting merely as the primary of a transformer of which the rotor winding is the secondary. By means of a

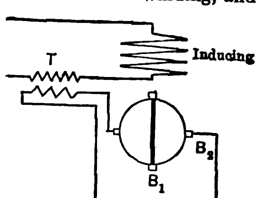

Fig. 4. Winter-Eichberg-Latour Motor

series transformer or compensator with taps the ratio of exciting current to main current may be changed at will and thus the speed and torque of the motor regulated. This is the principal advantage of this type of motor.

Series Repulsion Motor. — Since the repulsion motor has better operating characteristics at a speed near synchronism than the series motor it is better to run with repulsion motor connections. On the other hand, the series motor has better operating characteristics during starting conditions. These facts have lead to the development of the "series repulsion" motor by one of the manufacturing companies. In the control of this motor a compensator with numerous taps is used and the connections so arranged that during starting the armature receives a very large current while the field is excited below the normal value. This gives a considerable torque with little trouble from commutation. As the motor speeds up, the connections are gradually changed until at full speed the motor operates practically as a repulsion motor with the good commutating characteristics of that motor.

DIMENSIONS, WEIGHT AND COSTS. — Due to the low flux densities used and the special windings required an a-c. commutator motor weighs from 50 per cent to 100 per cent more, occupies from 25 per cent to 50 per cent more space, and costs from 50 per cent to 100 per cent more than a 600-volt d-c. motor of the same rating; see *Motors, Direct-current.*

MOTORS, DIRECT-CURRENT. — *(See also Alternating Currents; Electricity and Magnetism, Principles of; Generators, Direct-current; Motors, Industrial Applications of; Standardization Rules.)* A motor is a dynamo-electric machine for converting electrical power into mechanical power; that is, it performs the converse function of a generator. Direct-current generators and motors are always interchangeable in function, although a machine which is designed specifically for a motor would probably not make a first-class generator and vice versa. Motors of less than 5 horse-power are usually bipolar; larger machines are multipolar.

The following is a brief outline of the contents of this article:

CLASSIFICATION. — There are four types of direct-current motors, differentiated by their characteristics and the connection of the exciting windings or circuits.

Shunt Motor (Fig. 1). — This motor has only one exciting winding, which is connected across the armature terminals and is thus in parallel or in shunt with the armature. The field winding consists of a large number of turns of fine wire on each pole, and usually the windings on all the poles are connected in series in one circuit. The current in the field depends upon the line voltage and upon the resistance of the field winding. The resistance of the field winding is purposely made high so that the field current will be between 1 per cent and 5 per cent of the full-load current of the motor. The characteristic of the shunt motor is a fairly constant speed for all reasonable values of load.

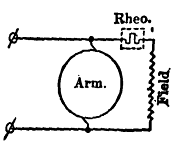

Fig. 1. Shunt Motor

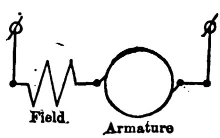

Fig. 2. Series Motor

Series Motor (Fig. 2). — This motor has only one exciting winding, which is connected in series with the armature so that all the current flows through the field as well as the armature. The field winding consists of a few turns of thick wire on each pole and the windings on all poles are connected in series. The current in the field depends upon the load and is thus large with heavy load and small with light load. The resistance of the field winding is purposely made low so that the loss of voltage and power in that circuit will be small. The characteristics of a series motor are a speed varying with every change in load,

high speed at light load and low speed at heavy load. The efficiency is high throughout a wide range of speed. The speed will be dangerously high at no load; thus a series motor must always be connected rigidly to its load. Since the torque is high at low speeds this motor is particularly adapted to work requiring frequent starting.

Compound (or Cumulative) Motor. — This motor has both a series winding and a shunt winding on each pole, wound and connected so that the two windings assist each other in the production of magnetism. It is a combination of a shunt and a series motor designed to give the good starting qualities of the series motor and to avoid the danger of excessive speed at light loads. See also *Motors, Industrial Applications of.*

Differential Motor. — This motor has a shunt and a series winding connected so that they oppose each other in the production of magnetism. The motor therefore has poor starting qualities, increases in speed with increase in load but has no tendency to run at a dangerously high speed. The applications of this motor are very limited.

Inclosed vs. Open Type. — These terms refer to the mechanical housing of the motor. The open type has all its parts freely exposed to the air and is therefore well ventilated. It is intended to be used indoors and in protected places. The inclosed type is intended to be used in exposed locations where there is a liability of dampness or dirt. Special means must be provided to circulate the air inside the machine, but even then an inclosed motor is larger and more expensive than an open motor of the same capacity.

The relative capacities in output of open, semi-inclosed, and totally inclosed motors are shown by the accompanying data on one of a line of typical commercial motors. In general an inclosed motor weighs about 15 per cent more than an open motor of the same capacity in spite of the fact that it is allowed to operate at 15° C. higher temperature by commercial convention.

Type	Output, h.p.	Temp. rise, °C.	Weight in lb. for 700 r.p.m. and given temp. rise
Open	10	40	970
Semi-inclosed	8	40	...
Totally inclosed	5.75	55	1100

METHODS OF RATING. — Motors are rated on the basis of either their continuous or their intermittent capacity.

The continuous rating of a motor is at present (1914) commonly taken as that output in horse-power (or kilowatts) which it will give continuously with a maximum rise in temperature measured by thermometer above the surrounding air at 25° C. not exceeding 40° C. on the field and armature and not exceeding 55° C. on the commutator; see, however, the *Standardization Rules of the A.I.E.E.*

The intermittent rating is at present (1914) commonly taken as that output which the motor will give for one hour (starting at room temperature) with a maximum rise in temperature by thermometer, above the surrounding air at 25° C., not exceeding 90° C. on the commutator and not exceeding 65° C. on any other part; see, however, the article *Standardization Rules of the A.I.E.E.*

VOLTAGE AND CURRENT. — Usual values of voltage for direct-current motors are:

110–125 for small motors on lighting circuits.
220–250 for motors in factories, shops, etc.; on power mains or on the outside mains of a three-wire system.
500–600 for general railway work.
1200 for special railway installations.

The current required for any motor is found by the relation

$$\text{Current} = \frac{\text{Output in h.p.} \times 746}{\text{Efficiency} \times \text{Voltage}}.$$

Usual values for the efficiencies of motors of various sizes are given below.

APPLICATIONS OF MOTORS. — This subject is treated in detail in a separate article on *Motors, Industrial Applications of* (q.v.). The chief applications of continuous-current motors are the following:

Shunt Motor. — Driving shafting, machine tools, blowers, reciprocating pumps; motor generators.

Series Motors. — Railway and all other transportation work; hoists; cranes.

Compound Motor. — Elevators, hoists and machinery that must be started often.

Differential Motor. — Very special applications of small units for peculiar speed conditions.

PRINCIPLES. — The principles upon which a direct-current motor operates are the same as those upon which a direct-current generator operates (*see Generators, Direct-current*). These principles are briefly as follows:

Force Acting on Conductor. — A conductor of length l carrying a current I and placed in a magnetic field having a flux density B is acted upon by a force which is proportional to BlI, which force is in a direction at right angles to the direction of the magnetic flux and at right angles to the length of the conductor.

This in practical form gives the relation

$$T = \frac{p\phi ZI}{852\, m \times 10^8}.$$

T = torque of an armature in pounds at one-foot radius.
p = number of poles.
m = number of armature paths between brushes.
ϕ = flux per pole in armature (lines).
Z = number of active conductors or coil sides on armature.
I = current taken by the armature from line.

This torque is exerted whenever a current flows and is independent of the speed. The core-loss and friction absorb some of the torque so that the torque at the pulley is slightly less than the value given by the formula.

Counter E.M.F. in Conductor. — A conductor of length l moving with a velocity V in a magnetic field of density B has induced in it an electromotive force E proportional to BlV. In practice as soon as the armature starts to move a counter e.m.f. is induced in its conductors which has the value

$$E = \frac{p\phi Zn}{m \times 10^8},$$

where n = revolutions per second.

Thus as soon as the armature moves, this counter e.m.f. tends to stop the flow of current and the impressed e.m.f. must be increased to maintain the flow of current.

The relation between current and counter e.m.f. is given by the equation

$$E_i = E + IR,$$

where E_i = impressed e.m.f.,
E = counter or generated e.m.f.,
R = resistance of armature circuit.

In practice R is made as small as possible so that E and E_i are as nearly equal as possible.

Reversing Rotation.— From a consideration of the equation for the torque it is evident that torque is proportional to the product ϕI, i.e., to the product of the flux in the armature by the current. If the direction of the current through the armature is reversed, that is, if I becomes negative, the product becomes negative and the torque is in the opposite direction. If the direction of the flux is changed (the armature current being unchanged) the direction of torque is reversed. But if both ϕ and I are reversed the torque is not reversed. From this follows the rule for reversing the direction of rotation of any direct-current motor; viz., change the direction of flow of current in either the field or armature winding but not in both.

Speed Control. — From the equation for counter e.m.f. it follows that the speed is proportional to E/ϕ. That is, the speed varies directly as the counter e.m.f. and inversely as the flux. Thus to reduce the speed, decrease the counter e.m.f. by decreasing the e.m.f. impressed on the armature or increase the flux by increasing the field current. To increase the speed perform the converse. To decrease the e.m.f. impressed on the armature a resistance may be inserted between the source of potential and the armature terminals. This is the customary manner of controlling the speed during the starting of motors. (*See also section below on Starting of D-C. Motors.*)

SHUNT MOTOR. — Since the flux in the armature of a shunt motor is practically independent of load, the characteristics of the motor are: approximately constant speed for all reasonable variations of load, torque directly proportional to the armature current irrespective of speed, efficiency high throughout a wide range of load but for only a small range of speed see Fig. 3.

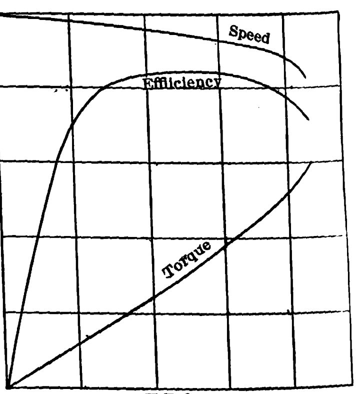

Fig. 3. Speed, Torque and Efficiency Characteristics of a Shunt Motor

Design of Shunt Motor. — The method of design and calculation of shunt motors is the same as for direct-current generators (*see Generators, Direct-current*) except for the minor details noted below.

The armature reaction of a motor is in the opposite direction to that of a generator running in the same direction, and thus the field is distorted in the opposite direction. Hence, if the brushes are to be moved to assist commutation they must be moved in a direction opposite to the direction of rotation of the armature.

The effect of armature reaction is to weaken the field. This causes a tendency to increase the speed and also causes bad commutation.

The stability factor of a motor must be greater than that of a generator because when the motor drops in speed as the load comes on, the field must be weakened to increase the speed. Hence the field is liable to be operated at an excitation less than normal.

Testing of Shunt Motors. — (*See also Standardization Rules of the A.I.E.E.*) The tests on shunt motors may be divided into two classes: (*a*) Commercial, to determine the qualities and serviceability of particular motors; and (*b*) Special, to determine the general characteristics and actions of a type of motor. Commercial tests are the following:

Resistance measurements.
Stray power test, including core-loss and friction.
Input-output test for heating, efficiency and commutation.
Insulation test.

Resistance Measurements are made with the machine cold and later after the heat run. The resistances of the armature winding and field winding are measured, and the brush-contact resistance may be measured but is usually calculated (*see Generators, Direct-current*). For any value of current the resistance losses (RI^2) are calculated from the measured hot resistances.

"Stray Power" Test. — The term "stray power" is applied to the lumped sum of the core-loss and the loss due to friction, bearings and windage. The stray power of a d-c. machine can be determined approximately by impressing normal voltage on the field and letting the machine run as a motor without load, varying the voltage impressed on the armature from about 10 per cent above normal to about 10 per cent below normal. The speed, armature voltage and armature current for each adjustment are observed. Then the stray power for any induced voltage is equal to the armature input less the corresponding RI^2, where R is the armature resistance and I the armature current. The value of stray power for any given load on the motor is then equal to the measured value corresponding to the same counter e.m.f. E, where E is calculated from the impressed voltage E_i by the relation $E = E_i - RI$, I being the armature current for this load and R the armature resistance as before.

If it is desired to determine the stray power more accurately by taking into account the effect of armature reaction, the field current may be adjusted so that the speed on the above run is the same as the load speed. This gives a flux of the same average value as when the machine is under load.

Calculation of Efficiency from Losses. — Let P = total output in kilowatts; R_a = resistance of armature, including brushes; I_a = armature current; I_f = field current; E_i = impressed voltage; S = stray power. Then the per cent efficiency is

$$\epsilon = \frac{100\,P}{E_i(I_a + I_f)} = \frac{100\,P}{P + E_iI_f + I_a^2R_a + S}.$$

Input-output Test with Prony Brake. — The input-output test may be made either by means of a prony or band brake on a pulley, or by using a d-c. generator as a load. If the brake test is made the output is

$$\text{Watts} = \frac{PLN}{7.04},$$

where P = net pull in pounds, L = lever arm or radius in feet, N = revolutions per minute.

Input-output Test with Generator as Load. — With large motors it is desirable to use a generator as a load in making an input-output test. In

this case it is necessary to know the resistance of the generator armature circuit. It is also desirable to have the generator separately excited and to maintain a constant excitation throughout the entire test.

The input of the motor and the output of the generator, together with the speeds of both machines, are observed. A "counter-torque" test must also be made to determine the belt friction loss and the core-loss and friction of the generator. This is performed by making two tests as follows:

(*a*) The motor input is observed when driving the unloaded generator at normal speed first through the regular leather belt and second through a light cotton belt. The difference in input to the motor in the first and second cases gives the belt-friction loss. As this loss is comparatively small, it may frequently be neglected.

(*b*) A regular stray power test (*see above*) is made on the generator when entirely disconnected from the motor. This gives the core-loss and friction of the load machine (generator).

Then for any load during the load run the output of the motor under test is

$$P_1 = P_2 + R_2I^2 + S + F,$$

where P_1 = output in watts of motor, machine 1.
P_2 = output in watts of generator, machine 2.
R_2I^2 = loss in armature winding of generator.
S = stray power of generator for speed and induced voltage at observed load.
F = belt-friction loss.

The ratio of this motor output to the electrical input as observed gives the efficiency of the motor.

Heat Run. — From the input-output test it is also possible to determine the speed regulation, commutation features and heating. The heat run may also be made by "bucking" two machines as described in the article on *Generators, Direct-current.* Small motors will reach a constant temperature in a short time and the heat run need only last 5 or 6 hours for a 100-h.p. motor. A thermometer is usually placed on the machine in a safe and accessible place and read every half hour until it indicates no further rise in temperature.

Insulation Test. — The margin of safety on a 110- or 220-volt motor is usually so great that it is not necessary to make an insulation test. If the motor has been exposed to dampness it may be desirable to make the test after the motor has been thoroughly dried out. The method is indicated in the *Standardization Rules of the A.I.E.E.* (q.v.)

Special Tests. — As a special test there may be obtained a saturation curve of the machine and possibly the distribution of potential around the commutator. These are of particular interest in an adjustable speed motor. In some of these motors with commutating poles there may exist some very high voltages between bars which are not evident except in the bar-to-bar potential test.

SERIES MOTOR. — Since the flux in the series motor is produced by the load current, the flux increases with the current. The torque is proportional to the product ϕI and therefore increases more rapidly than the current. Thus four times full-load torque can be obtained with from two to three times full-load current.

The characteristics of the series motor are: increase of torque faster than increase of current, variation in speed inversely as the load, and high efficiency throughout a wide range of speed as well as load, see Fig. 4.

Design of Series Motors. — In general the method of calculation is the same as for a direct-current generator (*see Generators, Direct-current*). The special considerations are:

A series motor is usually designed to have a large output and low speed at the one-hour rating. At any lesser output the speed will be higher, so the peripheral velocity must be quite moderate at the rated load and speed.

Since the speed is very nearly inversely proportional to the flux the speed curve depends on the shape of the saturation curve, to which very careful attention is paid in designing. By exactly fixing the flux for two extreme values of current the speed for these two values of current is fixed.

The relations between the speed and current of a series motor are shown by the formulas:

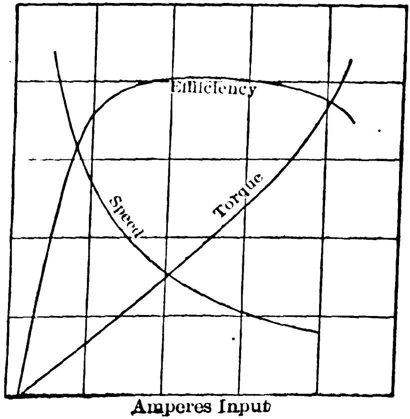

Fig. 4. Speed, Torque and Efficiency Characteristics of a Series Motor

$$E_i = E + IR,$$

$$E = \frac{p\phi Z n}{m\,10^8},$$

$$n = \frac{m(E_i - IR) \times 10^8}{p\phi Z},$$

where

E_i = impressed voltage,
E = counter e.m.f. induced in armature,
R = total resistance of armature and field,
I = current taken by motor,
p = number of poles,
m = number of parallel paths between positive and negative brush sets,
Z = total number of conductors on armature,
n = speed of armature in revolutions per second,
ϕ = total flux per pole in maxwells.

Since the current in the field of a series motor is the same as that in the armature, the ratio of the turns in each is the same as the ratio of ampere-turns or m.m.f's. Thus if the magnetomotive force per pole of the field is to be 1.5 times that of the armature the number of turns will be 1.5 times the number of turns in series in the armature.

Since a series motor is usually an inclosed motor with a one-hour rating its rise in temperature and rating are a direct function of the watts lost and the ability of the mass of the motor to store up this heat energy. In a one-hour run the amount of energy radiated is only about 10 per cent of the amount stored in the mass. For a rise in temperature of 75° C. in one hour there should be about 0.4 pound of material for each watt of loss. This assumes reasonable provision in the construction of the motor for the transfer of the heat from the armature to the field and frame.

Much attention has been directed recently to the ventilation of these motors by drawing air from outside the motor by means of fan blades on the armature and by circulation of the air inside the motor through definite paths. This has considerably increased the weight efficiency of these motors.

In railway motors, which are the most general application of the series motor, commutating poles are very generally used, as this construction makes it possible to obtain a much greater momentary output from a motor of a given size (*see below*).

Testing of Series Motors. — (*See also Standardization Rules of the A.I.E.E.*) To determine properly the speed and torque characteristics of a series motor an "input-output" test must be made, which involves subjecting the motor to actual load and overload conditions. This may be accomplished by running the motor with a prony brake as a load or with a direct-connected generator as a load (*see section above on Testing of Shunt Motors*).

Railway Motor Test. — When two similar motors are available the method used by the manufacturers of railway motors is most desirable. The two motors are direct connected, or geared to each other, and the electrical connections made as in Fig. 5. The test is run through by keeping constant rated voltage on the motor and regulating the load on the motor by changing the load on the generator.

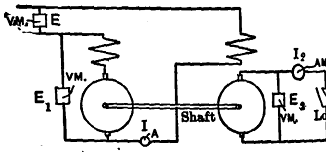

Fig. 5. Railway Motor Load Test

As the two machines are operating under almost exactly the same conditions, their efficiencies are very nearly the same. Thus

$$\text{Efficiency of set} = \frac{E_2I_2}{EI},$$

$$\text{Efficiency of each motor} = \sqrt{\frac{E_2I_2}{EI}}.$$

The speed and torque curves should be made for both directions of rotation of the armature as an incorrect brush setting will give results differing with the direction of rotation. The direction of rotation is changed by reversing the connections of either the field or the armature of the motor.

Commutation is observed during the speed and torque test.

The heat run is made with the same arrangement as the speed-torque test. In making the heat run the motor must start cold or at room temperature. The covers of the inspection openings of railway motors are customarily left open during the heat run.

Losses and Efficiency of Series Motors. — For a more accurate determination of the efficiency and losses the following special tests are made:

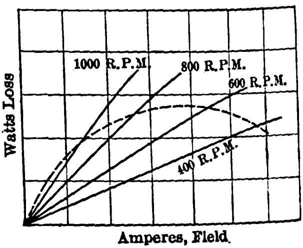

Fig. 6. Core-loss Curves of Series Motor

1. Resistance of armature, brushes and field. These tests are similar to those for a shunt motor, see above.

2. Core-loss test. On account of the variable speed and variable field of a series motor this test consists in repeating the usual core-loss test as described

above for a generator at several different speeds. The field strength is varied step by step throughout the maximum range for each speed. Fig. 6 shows the curves for these different runs and the dotted line connects the points on the different curves that apply to the normal speed curve of the motor.

Insulation Tests. — See *Generators, Direct-current,* and *Standardization Rules of the A.I.E.E.*

STARTING OF DIRECT-CURRENT MOTORS. — A starting box, Fig. 8, or rheostat is always employed in starting direct-current motors in order to reduce the voltage impressed on the motor when it is not running at a high enough speed to generate the proper counter e.m.f.

Let E_i = line voltage,
E = counter e.m.f. (approximately proportional to speed),
I = current,
r = resistance of armature circuit,
R = resistance of starting box or rheostat.

Then

$$I = \frac{E_i - E}{r + R}.$$

At the first instant the motor armature is stationary and $E = 0$; thus $I = \dfrac{E_i}{r + R}$ and the value of R is determined by the desired value of I. As the motor accelerates, E increases. If R remained constant I would decrease to such a small value that there would not be sufficient torque to accelerate the load. The current, and therefore the torque, can be brought back to their original values by changing R to such a value R_1, that

$$I = \frac{E_i - E}{r + R_1}.$$

Fig. 7 shows the sudden rise in current when the resistance is changed and the gradual decrease in current as the speed increases. The number of steps necessary depends upon the ratio of the maximum allowable instantaneous value of the current to the final constant value, upon the value of the armature resistance and upon the inertia of the load.

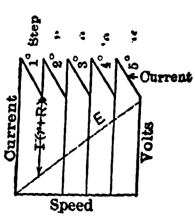

Fig. 7. Motor Current During Starting

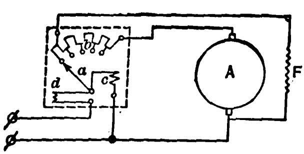

Fig. 8. Starting Box Connections for Shunt Motor

Starting Box.—(*See also article on Rheostats*). A starting box usually contains the following features, as indicated in Fig. 8: (a) a means of opening and closing the circuit supplying all the current to the motor including the field current; (b) a set of resistance steps in series with the motor armature and a means of short-circuiting this resistance step by step; (c) a magnet coil connected across the motor terminals to open the circuit if the impressed voltage fails or falls below a specified value (low-voltage release); (d) a magnet coil carrying the main current to actuate a spring and open the circuit if the current exceeds a

specified value (overload release). The usual connections of a starting box to the line and motor are shown in Fig. 8.

SPEED CONTROL. — There are three methods of varying and controlling the speed of d-c. motors, namely, potential, rheostatic and field systems.

Potential Control or Multi-voltage System. — By means of several generators and several wires various definite voltages are made available, such as 240, 180, 120, etc. By connecting the motor to the 240-volt circuit full speed is obtained; by connecting to the 180-volt circuit ¾ speed is obtained, etc. The shunt field circuit is left connected at all times to a circuit of the proper voltage. A shunt motor with normal field excitation will be stable, that is, it will operate constantly, at the fractional speed. The efficiency will be good at the fractional speeds. A series motor controlled in this manner will be unstable, but for a given torque the speed will be roughly proportional to the voltage.

Rheostatic Control. — A rheostat in series with the armature will reduce the voltage impressed on the armature by an amount proportional to the current, and thereby reduce the speed. The speed is unstable with this arrangement, changing with every change of load, and the efficiency is poor.

Field Control. — By increasing the resistance in series with the field of a shunt motor the speed is increased due to the weakening of the field. If the motor has commutating poles to assure good commutation the speed may be varied in a ratio of 1 to 2, and even 1 to 3 in small sizes. The shunt motor is stable with this method of control and the efficiency is good. In a series motor the field may be shunted by a resistance to increase the speed but the motor is not stable and this practice is not to be recommended.

USE OF COMMUTATING POLES (INTERPOLES) IN VARIABLE-SPEED MOTORS. — In motors intended to be operated over a large variation in speed, obtained by changing the field strength, and in motors which are to be subjected to heavy overloads, it is necessary to use commutating poles in order to obtain good commutation. In a motor without commutating poles the field strength must always be a certain percentage greater than the armature strength to prevent a shifting of the field flux and of the neutral point. Thus,

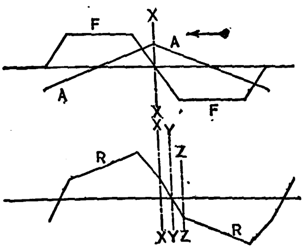

Fig. 9. Flux Distribution without Commutating Poles

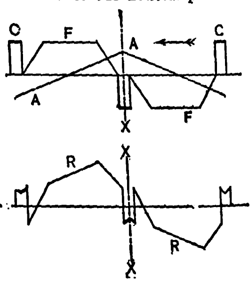

Fig. 10. Flux Distribution with Commutating Poles

if, in Fig. 9, F represents the distribution of field flux when existing alone and A represents a strong armature flux existing alone, then R shows the distribution of the resultant flux when both field and armature are excited.

It will be noticed that the neutral point has been shifted from XX at no load in a direction against rotation to YY at the load considered. The brushes would have to be shifted from XX at no load to a point ZZ beyond YY at load

in order that they shall commutate a coil in a flux which is producing a voltage helpful to commutation.

Resultant Flux with Commutating Poles. — If, however, commutating poles are placed between the main poles and excited with the armature current they will maintain at the geometrical neutral a flux of the direction and value necessary to give good commutation. In Fig. 10, *F* and *A* represent the field and armature flux separately as before and *C* the commutating pole flux that would exist at full load. When at full load these fluxes are combined there exists the resultant flux shown at *R*.

It will be noticed that there remains at the neutral point a small flux of the proper polarity and magnitude to provide an e.m.f. to reverse the current and give good commutation and it is not necessary to move the brushes.

The commutating pole must be of the same polarity as the pole towards which the brush would have to be moved if there were no commutating poles. In fact the principle of commutating poles is nothing more than bringing to the brush a part of the pole instead of moving the brush to the pole. Thus the polarity of the commutating pole is different during motor action from that during generator action. If the windings on the commutating poles are connected in series with the armature the conditions will be correct for either motor or generator action.

INSTALLATION AND ERECTION. — In the installation and erection of a direct-current motor there are certain features which must receive careful attention in order that the machine shall operate properly and not deteriorate with undue rapidity. Although this procedure varies with different motors according to their mechanical construction the following brief memorandum of points to be looked after will be found useful:

1. Base bolted down.
2. Bearings clean and filled with oil.
3. Bearings lined up.
4. Magnet frame bolted to base.
5. Field coils secured in place.
6. Field coils tested for open circuit, wrong connection and polarity.
7. Armature in place.
8. Air gap adjusted by shimming.
9. Measure resistance of armature and field.
10. Measure insulation resistance.
11. Brushes properly fitted and spaced and pressure adjusted to about 1.5 to 2 pounds per brush.
12. Commutator smooth and true.
13. Substantial connections of field circuit.
14. Field adjusted for correct direction of rotation.

The motor must be protected from moisture during shipment and if by accident it becomes damp it must be dried out before it is subjected to a voltage.

OPERATION. — In the operation of a direct-current motor several factors should be considered.

Care. — All motors should be frequently inspected and the following points noted:

1. Bearings filled with proper amount of oil.
2. Brushes securely held in proper position.
3. Brushes fit properly.
4. Commutator smooth: Danger of "high mica" or the insulation between commutator bars projecting above the bars.
5. Air gap true.
6. Commutator not worn in grooves.

Troubles. — In the following paragraphs is given a concise list of the troubles that may be experienced in operating continuous-current motors and their causes as given by Crocker and Wheeler in *Management of Electrical Machinery.*

1. *Sparking at the Commutator.* — Causes: Armature carrying overload. Brushes improperly spaced. Brushes not at proper position. Rough commutator. Poor brush contact. Internal short or open circuit. Field too weak. Unequal strength of poles. Vibration.
2. *Heating of Commutator and Brushes.* — Sparking. Bearing trouble. Bad connections. Brush friction too great.
3. *Heating of Armature.* — Overload. Internal short circuit, moisture or ground. Reversed coil. Excessive eddy currents.
4. *Heating of Field.* — Internal short circuit.
5. *Heating of Bearings.* — Bearings dry or dirty. Shaft out of true. Bearings out of line. Thrust due to belt. Unbalanced magnetic pull.
6. *Noise.* — Armature not balanced. Brushes dry or not set at proper angle. Armature strikes.
7. *Speed Too Low.* — Wrong voltage. Overload. Armature strikes. Bearing too tight.
8. *Speed Too High.* — Wrong voltage. Field too weak.
9. *Motor Stops or Fails to Start.* — Overload, open circuit, wrong connection.

SPECIFICATIONS FOR D-C. MOTORS FOR INDUSTRIAL USE.* — (*See next section for Specifications for Railway Motors.*) The following memoranda are intended to assist in writing specifications. See also article on *Specifications.*

Principal Characteristics and Conditions of Service. — Use to which motor is to be put, kind of load and method of drive. Voltage. Rating, horse-power. Speed.

Style and Description; Details of Construction. — Whether to be open, semi-inclosed or inclosed. Whether to be series, shunt or compound wound; if shunt wound, whether shunt field rheostat is to be supplied; if compound wound, state whether cumulative or differential. Requirements regarding pulley or length of shaft. Whether rails are required. Whether starting rheostat is to be supplied, and if so, its general characteristics.

Performance and Tests. — (*See Standardization Rules of the A.I.E.E.*). Temperature rises upon which ratings are to be based. Details of overload. Efficiency at 25, 50, 75, 100, and 125 per cent load; whether rheostat losses are to be included in calculating efficiencies. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Regulation; the supply voltage being constant, and the field rheostat fixed, a variation of load from zero to . . . per cent of full-rated load shall cause a variation of speed not greater than . . . per cent. The shunt field rheostat to give speed variation of . . . per cent in steps not greater than . . . per cent and not less than . . . steps, and to carry the current for any speed continuously without undue heating.

SPECIFICATIONS FOR SERIES RAILWAY MOTORS.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications.*

Principal Characteristics and Conditions of Service. — General statement of the service, giving type of cars, whether current is direct or alternating,

* By W. A. Del Mar.

or both, etc. The motor shall be designed for normal operation at . . . volts and shall operate safety at . . . volts.

Style and Description; Details of Construction. — The frame shall be designed so as to allow the easy removal of armature and field coils. It shall be provided with openings at both ends, and both above and below the shaft, which will enable the inside of the motor to be readily inspected and cleaned. Bearings shall be designed so that lubricant cannot enter the frame, and shall be so located that they may be easily emptied and cleaned. The diameter of the driving axle on which the motor is to be mounted shall be . . . inches. Whether motor is to be of interpole type. Whether natural or forced ventilation.

Brushes and Brush Holder. — The brush holders shall be readily removable through the hand holes. The springs holding the brushes against commutator shall not be relied on to carry current. The brushes shall be staggered or provided with adjustment parallel to the armature shaft so as to prevent the formation of ridges on the commutator.

Clearances.—The minimum distance between motor frame and back of wheel flanges shall be . . . inches, the minimum distance between bottom of motor and top of rail when tires are new shall be . . . inches.

Gears and Gear Case (if any).—Single or double reduction; what gear wheels shall be mounted on; material of wheel and pinion; description of teeth, whether cut or cast, and width of face of wheel or pinion; gear case, material, how suspended, oil-tightness.

Suspension of Motors.—General description and requirements, location of lugs on motor frames.

Data to be Furnished by Bidder. — The armature will be bound with . . . bands. Material and dimensions of the bands. Dimensions of openings in the frame. The brush holders will be adjustable so as to allow . . . inch wear with uniform pressure on the brushes, after the diameter of the commutator has been reduced by . . . inches. The current density in the carbon brushes will not exceed . . . amperes per square inch at normal rated load. The gear ratio will be . . .

Performance and Tests. — (*See also Specifications in article on Locomotives, Electric.*) Either the nominal rating and the continuous ratings at ½, ¾ and full voltage should be specified, or the following data supplied.

Line voltage..
Number of motors per car..............................
Weight of loaded car, exclusive of motors and control equipment.
Diameter of driving wheels............................
Schedule speed..
Distance between stops................................
Duration of stops.....................................
Acceleration miles per hr. per sec....................
Retardation, miles per hr. per sec....................

The engineer should also give a diagram of grades and curves.

Motor Characteristics. — The bidder shall submit diagrams showing speed, tractive effort, efficiency, RI^2 losses, core losses, and any other information bearing on the performance of the motor. Requirements regarding the effect of moisture upon insulation.

Tests. — The motor shall be tested at the Manufacturer's works in the presence of the Engineer's inspector. (In the case of new motor developments it is good practice to make the tests under service conditions; but for standard motors a stand test at the factory is sufficient.) A complete series of tests shall be made upon the first motor manufactured under this specification. These tests shall confirm all the statements made by the bidder in relation to operating characteristics. Should the motor fail to comply with any of these statements, the defects shall be corrected and any changes in construction or design which may be necessary to accomplish this shall be made at the contractor's expense. The first motor shall be submitted to a flashing test to determine the susceptibility of the motor to flash-over on opening the maximum specified line voltage across the motor when running at maximum speed. After the acceptance of the first equipment, any other motors to be supplied under this specification shall be submitted to an approved stand test. The insulation of the armature windings, commutator and field windings, shall be subjected to stated alternating voltages (*see Standardization Rules of the A.I.E.E.*) for a period of one minute.

PERFORMANCE, WEIGHT AND COST. — Usual values of the efficiency and losses, and also values of the weight, speed and cost of shunt and series motors are given in the following tables.

PERFORMANCE OF SHUNT MOTORS

H.P.	Full load efficiency, per cent	Field I^2R, per cent	Friction, per cent	Core-loss, per cent	Armature I^2R, per cent
0.5	70	5	10	5	10
1	79	4	8	4	5
2	82	3.5	7	3.5	4
5	85	3	5	3	4
10	87	2.5	4.5	2	4
20	88	2	4	2	4
25	89	2	3	2	4

WEIGHT, SPEED AND COST OF SHUNT MOTORS

H.P.	Speed, r.p.m.	Weight, pounds	Cost	Speed, r.p.m.	Weight, pounds	Cost
0.5	2200	60	$30	....	....	...
1	2000	100	50	1675	125	$60
2	1650	210	75	1175	250	90
5	1100	650	160	920	600	165
10	850	950	240	700	1100	280
20	680	1650	410	550	1900	470
25	650	1950	500	500	2300	600

PERFORMANCE OF SERIES MOTORS

Commutating Pole Railway Type

H.P.*	Full-load efficiency, per cent	Field I^2R, per cent	Friction, per cent†	Core-loss, per cent	Armature I^2R, per cent
40	79	6.5	5.3	2.2	7.0
50	82	5.0	5.0	2.1	5.9
75	84	4.5	5.0	2.0	4.5
100	85	4.3	5.0	2.0	3.7
150	86.5	3.5	5.0	2.0	3.0

* H.P. for 75° C. rise in one hour.
† Friction includes loss in gearing.

WEIGHT, SPEED AND COST OF SERIES MOTORS

Commutating Pole Railway Type

H.P.*	Speed, r.p.m..	Lb., weight per h.p. †	Cost, dollars per h.p.
40	750	57	11
50	700	53	10.5
75	650	44	8.5
100	625	37	7
150	600	33	6.4

* H.P. for 75° C. rise in one hour.
† Weight includes cast-steel frame and gear pinion and gear case.

MOTORS, INDUSTRIAL APPLICATIONS OF.—(*See also Bearings; Belts and Belting; Blowers and Compressors; Chains and Chain Drive; Conveyors; Couplings, Direct; Cranes; Dredges, Electrically-Operated; Elevators, Electric; Fans; Flywheels for Load Equalization; Gears and Gearing; Hoists, Electric; Machine Tools, Electrical Operation of; Motors, A-C. Commutator, Direct-Current, Polyphase Induction, Single-Phase Induction, Synchronous; Pumps and Pumping Engines; Printing Presses; Ropes and Rope Drive; Shafting; Shovels, Electrical Operation of; Steel Mills, Electric Drive of; Telpherage; Unloaders, Coal and Ore; Valves.*) The application of the electric motor for driving industrial machinery, either individually or in groups, was at first thought to be of value merely in the saving of power through the elimination of the losses due to friction in line shaftings or other forms of mechanical transmissions. A still higher economy has, however, been found to lie in the remarkable effect that it has in increasing the output of the production.

ADVANTAGES OF ELECTRIC DRIVE. — The more important advantages of electric drive are the following:

Location of Machines. — The various machines can be placed in almost any desired position and the use of portable tools is readily made possible, as, for example, when a portable drill and slotter are brought to a heavy casting, the slotter being applied to the outside of the piece at the same time the inside is being drilled.

Head Room. — A clear head room is obtained by the elimination of belting. This gives better illumination and ventilation and permits overhead cranes to be used freely, which is of greatest importance in any factory as it greatly facilitates the handling of the material, resulting in a considerable saving in time and labor, and thus increasing the output.

The constant source of dripping oil from overhead bearings and shafting is eliminated, and the danger which always accompanies the use of belts is overcome.

Centralized Power. — Power can most readily be distributed from a central supply station to the different buildings, and changes or additions to the system can always be made without difficulty.

Reliability. — The electric system offers greater reliability than belt drive. A breakdown is usually confined to a single machine, but with belting and a shafting a breakdown will generally cause a shutdown of a considerable portion of the equipment.

Study of Machine Performance. — Meters of either the recording or indicating type can be installed easily where desired and the performance of every individual machine ascertained. This is a very important point in all industrial undertakings, as it is then possible to maintain all the machinery in the best operating condition. Any excess power taken is at once readily detected and the defect can be promptly corrected. An accurate record can also be kept of the cost of power for the different operations.

GROUP VERSUS INDIVIDUAL DRIVE. — There are two general systems of drive, namely, group and individual, and there is still a diversity of opinion as to the relative advantages of the two. The group drive is to a certain extent an outgrowth of the older system of line shafting. When such a system is to be changed to an electric drive, the most obvious and simple way of making the change is to split the shafting up into such sections as would be most convenient, and drive each of these by means of a comparatively large motor. On the other hand, it may frequently happen that it is necessary to operate only one machine of the entire group for a considerable time, as in overtime work,

and to do this it would then be necessary to keep the motor and the line shafting of the whole group running. Since the efficiency of the motor at this light load would be small, and the friction losses of the entire drive would have to be supplied, it is evident that such a method of operation would result in a waste of power and be most inefficient. Modern installations, therefore, indicate a tendency toward the use of both the group and individual drive.

Influence of Character of Load. — It is generally agreed that all large tools or other machinery should be equipped with individual motors, especially if their service is of an intermittent nature. With the group drive there are two distinct loads, the variable of the machines and the friction of the line shafting and belting. The lower the machine load factor, the greater becomes the percentage of friction load and the more inefficient the group transmission.

Influence of Speed. — Wide ranges of control and the possible variations of speed are reasons which in many cases are sufficient in themselves for the selection of an individual drive. With group drive the methods of speed control for the individual machines are obviously more limited. It is then generally accomplished by shifting of belts on cone pulleys or by change of gears. Both of these methods, however, take a considerably longer time than the simple manipulation of the controller with the individual electric drive.

With individual motor drive it is possible to obtain very fine speed graduations, this benefit, of course, only being derived with a variable speed motor. Another advantage is the fact that it is possible to speed up a machine with a proportional increase in power. This may be necessary whenever a change is made from carbon to high-speed steel.

Influence of Relative Cost. — The increased cost of installation is one of the principal factors that prevent the general installation of individual drives. With this drive the total horse-power rating of the motors installed in the plant will be considerably greater than with group drive, but the maximum power demand of the plant is approximately the same in either case. If power is purchased the price should be based on the actual maximum power demand and not, as sometimes is required, on the total connected horse-power capacity of the motors. This latter method would obviously give a lower basic rate for the group drive, although the higher efficiency of the individual drive would considerably reduce the actual power consumed.

The question of whether or not group or individual drive is to be installed is thus a financial one and each case must be properly analyzed. Individual drive necessarily means a larger investment, but in nearly all cases a much greater percentage income will be realized than if line-shaft drive were employed.

GENERAL CONSIDERATIONS IN THE SELECTION OF MOTORS. — The conditions of capacity and efficiency are both of importance in any motor installation and should therefore be given careful consideration. The installation of a motor having too large a capacity should in general be avoided, unless an increase in the load is to be expected in the near future, because the efficiency of a motor is usually a maximum at its normal rated output, decreasing above and below this point. With alternating-current motors the effect of the power factor must furthermore be considered. This decreases rapidly below normal load, and on account of its bad effect on the regulation of the system it should be kept as high as possible, which can only be done by operating the motors as nearly fully loaded as possible. Ordinarily, however, it is possible to so group the machinery that the motors may be operated near their rated output at all times. Too small a motor is naturally also very undesirable, as it would then in all probability be subject to overloads, which may result in overheating and a burn-out of the motor, causing a shutdown, not only of the motor itself, but also of the machinery which it drives. The op-

erating conditions of the plant may furthermore be such, as for example in steel mills, that the failure of a single motor may necessitate the shutting down of the entire mill.

The selection of suitable motors requires not only complete information on the power required to drive each group of machines or each machine individually but also a thorough knowledge of the motor design and its inherent characteristics to meet the requirements of the load. Some machines will require motors with very heavy starting torque, although running under light load when up to speed, while for others the requirements may be just the opposite. With a variable speed motor the torque-speed characteristics should agree as nearly as possible with the load which the motor is to drive, and the characteristics of adjustable-speed motors as influenced by different systems of control should also be carefully investigated. See also section below on *Data Required to Determine Type and Size of Motor.*

Influence of Motor Efficiency. — A motor of high efficiency is obviously desirable, and it is generally an easy matter to estimate the saving incurred by the installation of a motor of high efficiency as compared to a less efficient one. When a motor is operated for a considerable part of the time on light load, this fact must be given due consideration in the comparison on account of the variation in the motor efficiency for different loads.

Influence of Torque and Speed. — In order to obtain the most satisfactory results from motor drive it is essential that the type as well as the size of the motor be properly adapted to the work contemplated. This is especially important in the case of individual drive, where a wrong selection of the proper motor would be more serious than in group drive. The size of the motor may be ample to operate the machine under normal load but it may not be able to develop a sufficient starting torque, or it may draw a too excessive starting current from the line. For example, to start and accelerate the bridge of a crane requires a motor capable of developing a high starting torque, but after the bridge is accelerated comparatively little power is required to keep it in motion.

The condition of maximum torque must also be given due consideration. A motor driving a heavy punch may, in spite of the flywheel, develop insufficient torque to keep up the speed. As a rule, however, where the motor is large enough for starting and normal operation, but not large enough for the maximum overload required for perhaps only a second or two, the addition of a suitable flywheel will sometimes cut down the maximum torque required. In other cases it may be necessary to install a motor larger than necessary for the average work.

The proper speed regulation is also of importance and a motor must be selected which is best meeting these requirements. The size of the motor is also influenced by the cycle of operation, i.e., whether the load is continuous or intermittent. Careful consideration should be given to this point, and, as previously mentioned, motors will undoubtedly soon be rated to conform to the particular service for which they may be required. See also section below on *Classification of Motors According to Speed.*

Alternating Versus Direct Current. — The choice of alternating or direct current depends largely on local conditions and on the service requirements. With all other conditions the same, the alternating-current system offers many advantages when the distances over which the power must be transmitted are large. A higher transmission voltage may be selected which will diminish the amount of copper needed in the line conductors. The conditions may be such that high-voltage motors can be used, but in other instances step-down transformers may have to be provided and the expense of these as well as other auxiliary apparatus connected therewith must then be considered. It is gener-

ally conceded that the alternating-current system is more reliable than the direct current. This is mostly due to the absence of commutator trouble and to the rugged design of the induction motor.

There is no reason for installing direct-current motors except where a variable speed service is required, and in small plants where such a service is predominating the direct-current system would naturally be the one to install. If the variable-speed feature is only required intermittently, the phase-wound induction motor may be used to advantage. As a rule, a considerable part of industrial machinery will require a constant-speed service, for which the alternating-current motor is admirably adapted, and should direct current be required it can be obtained by installing a motor-generator set.

As a rule it may be said that the alternating-current system should be selected if possible. This would furthermore permit of throwing over to a central-station service, in case it should be found that power could be more economically purchased from the central station than generated on the premises.

CHARACTERISTICS OF MOTORS AFFECTING THEIR APPLICATIONS. — (*See also the separate articles on Motors.*) Motors are divided into two classes — direct-current and alternating-current, according to the system from which they are operated. The direct-current motors are further subdivided into three types, namely, series, shunt and compound motors.

There are also three general types of alternating-current motors, namely, induction, synchronous and commutator motors.

Series Motor. — This motor is used when a powerful starting torque and rapid acceleration are required, without an excessive instantaneous demand of energy. The torque is practically independent of the voltage and at low flux densities varies directly as the square of the current, but as the magnetization approaches saturation it becomes more nearly proportional to the first power of the current. The maximum torque exists at low speed, this being the most valuable feature of the series motor. Dangerously high speeds may be attained by the armature with very light loads, and series motors should for this reason be either geared or direct connected to the load.

Speed Control of Series Motor. — The speed of a series motor on constant potential varies automatically with the load, increasing as the load decreases. The speed may, however, be adjusted if some means of varying the impressed voltage is provided. As the work required of a series motor is very often intermittent in character, the insertion of resistance in the armature circuit to reduce the speed is permissible from an economic standpoint in such cases. In others, such as railway work, where two or four motors are used, reduced voltage is most readily and economically obtained by connecting the motors in series or in series-parallel.

Shunt Motor. — This motor has good starting characteristics and a practically constant speed, varying only slightly with load changes. The speed can, however, be adjusted, either by changing the e.m.f. impressed on the armature, or by changing the field flux.

Speed Adjustment by Armature-voltage Control, i.e., by changing the e.m.f. impressed on the armature, does not change the full-load torque which the motor is capable of exerting, since the rated torque depends only upon field flux and rated armature current. These methods are therefore constant-torque methods and are properly adapted to loads in which the torque remains constant regardless of speed. The method most generally used for varying the impressed e.m.f. with a single-voltage system is by means of inserting resistance in series with the armature. The efficiency with this method is, of course, very low at slow speeds. The speed regulation with varying loads may also be very poor.

There are several systems of controlling the motor speeds by applying different voltages, such as by the use of three-wire generators or two-wire generators with balancer sets or by the Ward Leonard system. This latter system, which is the most practical, consists of a constant-speed motor driving a generator which supplies current to the motor whose speed is to be adjusted. This arrangement is very satisfactory but on account of the expense of providing three full-sized machines instead of one to perform the work, the cost may be prohibitive except with very large motors, such as for hoists, etc.

Speed Adjustment by Shunt-field Control, i.e., by inserting resistance in the shunt-field circuit, is the simplest of all methods of speed variation, but with ordinary shunt motors, the range of speed variation by this means is small. Where a variation of more than from 20 to 30 per cent is desired, a motor of modified design and of a certain increased size is generally required, because the field must be more powerful with respect to the armature than in the case of standard single-speed motors. Variable-speed motors of the field-weakening type are not constant torque, but constant-output motors, i.e., the torque falls proportionally as the speed increases.

A speed variation up to 3 to 1 meets, as a rule, all requirements and such motors can readily be obtained in commercial sizes. Should a greater speed variation be desired, say 4 to 1 or 5 to 1, it is possible to accomplish this by the commutating-pole shunt motor with field control only. A combined field and armature control would, however, be a better method.

Compound Motor. — This motor is provided with both a series and a shunt field. The two fields are usually connected so that they act in the same direction, in which case the motor is called a "cumulative" compound motor. "Differential" compound motors, with the two fields opposing, are sometimes employed for special services. The cumulative, or ordinary, compound motor combines the characteristics of the shunt and series motors, having a speed not extremely variable under load changes, but developing a powerful starting torque and an increasing torque with decreasing load. Motors having a comparatively weak series field are employed extensively in shop practice where the motor may be required to start under heavy load but must maintain an approximately constant speed after starting, or when the load is removed. The heavily compounded motor is used where powerful starting torque and rapid acceleration are necessary, with a speed not varying too widely under load changes, such as for rolling mills, etc.

The speed control employed with compound motors may be any of the various methods explained in connection with the shunt motor. For certain service the control may be entirely rheostatic, the series winding being cut out after the motor has come up to speed.

Induction Motor. — The induction motor is essentially a constant-speed machine, although the speed may be varied either by varying the applied stator frequency or by introducing resistance in the rotor circuit. It is built in two distinct types, namely, the squirrel-cage and the phase-wound.

Squirrel-cage Motor. — The squirrel-cage type is used for constant-speed service with infrequent starting. It has a relatively small starting torque per ampere and draws a large starting current from the line. By increasing the resistance of the rotor, it may however also be built in the smaller sizes for a high starting torque, rapid acceleration and frequent starting, for such applications as sugar and laundry centrifugals, etc., where simplicity of control is desirable. They are also used for operating punches, shears, etc., where a flywheel is provided for storing the energy.

Induction Motor with Wound Rotor. — For service requiring high starting torque combined with moderate starting current a motor with the wound

type of rotor is best adapted. A motor with the resistance mounted inside the rotor should not be used to operate machinery having large inertia or excessive static friction, since full starting current may be required for a long period before the apparatus attains full speed, and, as the capacity of the internal resistance is small, excessive temperatures may result. This type of motor is, as a rule, not built above 200 horse-power due to mechanical difficulties involved in connection with the internal resistance.

A motor with external resistance should be used for moderate and large sizes. The rotor must then be provided with collector rings and brushes. The contact resistance of these as well as the leads and the controller fingers, which are in the circuit all the time, may impair the efficiency and regulation of the motor, especially if the controller and the resistance are located some distance from the motor. The phase-wound induction motor with an external variable rotor resistance is best adapted for a variable-speed service, as the losses necessary to obtain reduced speeds are external to the motor itself.

Multi-speed Induction Motors. — It often happens that the service is such that two or three speeds will be satisfactory for the operation of the machinery and that these speeds must be independent of the load. Under such conditions multi-speed motors can frequently be used. In these motors the different synchronous speeds are produced by changing the number of poles in the magnetic circuit. Each of these speeds is fixed, if no resistance is used in the secondary circuit. With multi-speed motors, as with single-speed motors however, resistance may be used in the secondary circuit for varying the speed.

A change of the number of poles may be produced in any of the following ways:

1. By the use of single magnetic and electric circuits, changing the number of poles by regrouping the coils.
2. By the use of single magnetic circuits and independent electric circuits.
3. By means of separate magnetic and electric circuits, the so-called Cascade connection.

Synchronous Motor. — The speed of a synchronous motor is constant, being fixed by the number of poles and the frequency of the applied voltage. The single-phase type is not self-starting and the polyphase type has in itself a very poor starting torque. They may, however, be made self-starting in the same manner as squirrel-cage induction motors, by the use of an ammortisseur or cage winding, similar in construction to that used for induction motors.

The speed-torque curve of a synchronous motor is similar to that of an induction motor except that the torque values are lower for a given resistance of rotor winding on account of the construction of the machine. The starting winding must be designed with both the load at start and the load at synchronous speed in mind, because too great a slip may cause the motor to shut down when the field is put on. It is, however, seldom that the same motor will be called upon to start a heavy load and at the same time synchronize a heavy load, as the load usually consists principally of either static friction, as in the use of motor-generator sets, line shafting, etc., or it comes up with the speed as in the case of a fan blower or centrifugal pump. The former case would be met by a high-resistance squirrel-cage winding and the latter would require a low resistance.

Single-phase Series Motor. — This type of commutator motor has a very powerful starting torque, high power factor and relatively high efficiency. It is most generally used for traction work, the speed being controlled by varying the applied voltage, which can most readily be done by means of an auto-transformer with a number of taps.

Repulsion Induction Motor. — This type of commutator motor has a limited speed and an increase of torque with decrease in speed. The action of the compensating field insures a power factor approximately unity at full load and closely approaching unity over a wide range in load. In addition it serves to restrict the maximum no-load speed and also permits, where varying speed service is involved, an increase over the synchronous speed.

Starting of Repulsion Motors. — A repulsion motor, if started by directly closing the line switch, will develop about 2½ times full-load torque. The starting current corresponding to full-load starting torque is from 2 to 2¼ times full-load running current. As a general rule, starting boxes are not required up to and including 2 horse-power rating. From 2 to 5 horse-power the use of a rheostat is optional, dependent upon the degree and care to be exercised in maintaining voltage regulation. Starting boxes should, however, preferably be used on sizes above 5 horse-power, especially where light and power circuits are combined.

Reversible Repulsion Motors. — The repulsion motor may be designed for reversible service. This is accomplished by adding an auxiliary reversing winding spaced 90 degrees from the main field winding and connected in series with it. By reversing the relative polarity of the two windings, the direction of rotation is changed in a simpler manner than by mechanical shifting of the brush holder yoke. Instant reversal may be effected from full speed in one direction to full speed in the other, about 200 per cent of normal running torque being developed at moment of speed reversal in either direction.

Variable-speed Repulsion Motors. — In addition to the constant-speed repulsion motor, two other types are also available, one for constant-torque and variable-speed service, the other for adjustable speed independent of torque. In general, variable-speed repulsion motors are not applicable to lathes, boring mills or similar machines where the service requires adjustable speed and constant horse-power at all speeds below and above normal. When a certain amount of variable speed is required at approximately constant torque, such as driving fans, blowers, printing presses, etc., the repulsion motor successfully meets a wide field of application.

POWER RATING OF MOTORS. — (*See also Standardization Rules of the A.I.E.E.*) These rules recommend that with the exception of railway motors, all motor ratings shall be expressed in kilowatts (Kw.) available at the shaft. On account of the hitherto prevailing practice of expressing mechanical output in horsepower, it is, however, also recommended that for machinery of this class the rating may, for the present, be expressed both in kilowatts and in horsepower, as follows: Kw. ——— h.p. ———. The horsepower rating of a motor may for practical purposes be taken as 4/3 of the kilowatt rating.

It is also highly desirable that the motor ratings should closely conform to the actual service requirements, and for this reason the Standardization Rules also recommend the following two kinds of ratings:

1. **Continuous Rating,** when the motor shall be able to operate continuously at its rated output, without exceeding any of the guaranteed limitations.

2. **Short-Time Rating,** when the motor shall be able to operate at its rated output during a limited period, to be specified in each case, without exceeding the guaranteed limitations. Such service includes runs alternating with stoppages of sufficient duration to ensure substantial cooling.

CLASSIFICATION OF MOTORS ACCORDING TO SPEED. — Motors for industrial application may be conveniently classified according to their speed characteristics. The wording of the classification as adopted by the American Association of Electric Motor Manufacturers is as follows:

A. — Constant-speed Motors, in which the speed is either constant or does not vary materially, such as synchronous motors, induction motors with small slip, ordinary direct-current shunt motors, and direct-current compound-wound motors, the no-load speed of which is not more than 20 per cent higher than the full-load speed.

B. — Adjustable-speed Motors. — 1. Shunt-wound motors in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load, such as motors designed for a considerable range of speed by field variation. 2. Compound-wound motors in which the speed can be varied gradually over a considerable range, as in 1 and, when once adjusted, varies with the load, similar to compound-wound constant-speed motors or varying-speed motors, depending upon the percentage of compounding.

C. — Varying-speed Motors, or motors in which the speed varies with the load, decreasing when the load increases, such as series motors and heavily compounded motors. Examples of heavily compounded motors are those designed for bending roll service and mill service, in which a shunt winding is provided only to limit the light-load operating speed.

D. — Multi-speed Motors (two-speed, three-speed, etc.), which can be operated at any one of several distinct speeds, these speeds being practically independent of the load, such as direct-current motors with two armature windings and induction motors with primary windings capable of being grouped so as to form different numbers of poles.

DATA REQUIRED TO DETERMINE TYPE AND SIZE OF MOTOR. — In selecting a motor for a certain application complete information must be had with regard to the machines to be driven. This is the first step and in some respects one of the most important parts of the problem, as without complete information on the subject it becomes very difficult, and in certain instances utterly impossible, to intelligently select or design a motor and control equipment which will satisfactorily fulfill the conditions to be met in actual operation. In order to facilitate the work of obtaining such information, an outline of the points to be investigated is given below.

1. Description of Machine to be Driven. —

a. Individual or group drive.

b. Photographs, drawings and sketches of machines and connections as complete as advisable, especially such drawings as indicate the size of heavy flywheels or rotating masses whose speed must be varied, and also drawings indicating gearings, transmission devices, etc.

c. Limiting features of product. What are the points in quality and characteristics of product which fix the condition of operation? e.g. limiting speed of tool or mechanism, etc. *Example:* A 26-inch lathe used for finishing requires approximately 3 horse-power to drive. The same lathe for roughing shafting, when equipped with high-speed tool steel and two tools, needs approximately 30 horse-power.

d. Can electric drive approach nearer the conditions wanted?

e. If group drive can be considered for several machines, some of which are only to be operated intermittently, give notes with regard to the latter machines.

f. What arrangements can be made so that intermittently-operated machines need not operate simultaneously, thus giving a smoother load curve and allowing the use of one small motor to drive several intermittent machines?

2. **Cycle of Operation.** —

a. Starting condition. Torque at start of day, and start of each cycle. Is frequent starting and stopping necessary? *Example:* The adjustment of large boring mills affects the controller, etc. Starting torque may be measured approximately if necessary by adjusting a rough beam to shafting. Find distance from axis at which the weight just starts machine. Knowing the weight in pounds the torque may be calculated.

b. Curves of loads, speeds, torque, maximum and average conditions through one complete cycle. Where necessary note power required with machines both loaded and unloaded. From this may be determined losses in shafting and transmission.

c. Time in operation, days per year, per month, per week, hours per day.

d. Reversing conditions, their frequency, their time, full or partial. Some apparatus, e.g., lathes, printing presses (flat-bed type), etc., only require slight backward movement to release tool or to adjust cylinders.

e. Starting. Flywheel or line shafting, friction clutches, etc.

f. Are speeds, torques, accelerations, etc., fixed by conditions of work or of driving machine?

g. Can any parts of cycle be varied with benefit? This should be investigated carefully.

3. **Present Method of Drive.** —

a. Prime mover or source of power.

b. Method of speed variation and speed change or control. Must machine be shut down to change speed?

c. Adaptability to gearing, etc.

d. Speed of machine, size of pulley, size of belt, size of gear or chain.

4. **Mechanical Transmission.** —

a. Rope, belt, chain, gear, direct connection. Direction of pull on belt or gear. Is belt or chain pull on the top or bottom? Is belt tightner advisable?

b. Clutches. Crab clutch, friction or couplings. Rigid, flexible or insulated.

c. Method of speed variation.

d. Brakes, electric. Solenoid or magnetic. Regenerative control, dead load or pumping back.

e. Brakes, mechanical. Band-post brake, disc brake, automatic safety brake, steam, hydraulic, air- or hand-operated.

5. **Conditions of Location.** —

a. Near external source of heat, furnace, etc.

b. Character of dust, conductive, magnetic or wearing, marble or stone, etc.

c. Possibility of fire or explosion to be caused by sparks from motor. Combustible flyings, e.g., cotton mills.

d. Explosive gases. Coal gas, benzine fumes, etc.

e. Presence of injurious gases. Acid fumes or salt air, e.g., SO_2, Cl, etc.

f. Dampness and moisture.

g. Insurance regulations. Obtain and forward copy of State Insurance Rules, or other state or local regulations, e.g., mining laws, municipal laws. Consider also personal danger or liability due to use of high-voltage apparatus.

h. Accessibility for inspection and repairs, oiling, etc.

i. Ventilation.

j. Allowable space for installation, also space for transportation. Down mine shaft, through doorways, etc.

k. Foundations and how attached to same.

l. Sudden temperature variations. This may cause condensation of moisture on windings and insulation.

m. If controlled from distance where will controller or switch be placed? Give approximate length of leads necessary. Must they pass through or under water, in building, on poles, underground?

6. Control. —

a. Intelligence (probable) of operators.

b. Is entire range of operation visible to operator or are special automatic features desirable?

c. Regenerative Control — See item No. 4-*d;* also *Cycle of Operation,* item No. 2.

7. Overload and Safety Devices. —

a. Can electric automatic devices be made to supersede mechanical overload safety devices, such as slipping clutches, braking shafts or crabs?

b. Should these devices be time limit or instantaneous? If former, how long?

c. Are safety devices necessary, other than those to protect overload — e.g., overrun of hoist, stoppage or cessation of load. Must emergency stop be employed, and where placed?

d. Are no-voltage releases required or advisable?

8. Probable Cost of Present Method of Operation. —

a. *Steam Operation.*

1. Coal. Tons per day or month; quality, cost, distance shipped.
2. Feed and other water. City mains or pumped; source, quality.
3. Is steam required for other purposes beside power? e.g., digesters, heating, etc.
4. Can steam be generated from waste gases or other waste products?
5. Distance of transmission, outdoors and indoors.

b. *Air.* Distance of transmission, air pressure, how obtained?

c. *Water Power.* Has electric installation to compete with water power? If so, report separately on this aspect.

9. Strength of Present Equipment. —

a. Strength of line shafting, foundation, transmission or gearing, machine parts.

b. Give estimate of limiting horse-power of items in (*a*), using sketch and dimensions where necessary. The above items should be considered with regard to any change in speed or torque made necessary or desirable, due to the electric drive.

10. Generating Station or Source of Electric Power. — Capacity of station or feeder, frequency, voltage, location, voltage or frequency variations.

BIBLIOGRAPHY. — It is impossible in the limited space available to give references to all the numerous papers in the technical journals dealing with the industrial applications of motors. The reader should consult the files of the *Transactions of the American Institute of Electrical Engineers, American Society of Mechanical Engineers, National Electric Light Association; also the Electrical World, General Electric Review, Electric Journal, Electrical Review, Power, Power and Engineer, Electrical Engineer, Engineering Magazine, Cassiers' Magazine.* A few recent papers are listed below.

MOTORS, POLYPHASE INDUCTION. — (*See also Electricity and Magnetism, Principles of; Generators; Motors, A-C. Commutator, Direct-current, Single-phase Induction and Synchronous; Motors, Industrial Applications of; Standardization Rules; Transformers.*) An induction motor may be either single, two, or three phase. Single-phase induction motors are treated in another article (*q.v.*). The induction motor is essentially a polyphase transformer with the secondary free to move; the electric energy transferred to the secondary is transformed by this motion directly into mechanical energy.

The following is a brief table of the contents of this article:

DEFINITIONS AND PRINCIPLE OF OPERATION. — Certain terms used in connection with the induction motor can best be defined by a brief statement of the principles underlying its operation.

Primary and Secondary. — By the primary of an induction motor is meant that part which receives energy by direct connection to the source of electric energy; the other member is called the secondary.

Stator and Rotor. — That member of an induction motor which remains stationary, whether it be the primary or secondary, is called the "stator," and the revolving member is called the "rotor." In most machines the primary is the stator. A "squirrel cage" rotor is one in which the conductors are straight bars of copper all connected together at each end of the rotor by copper rings.

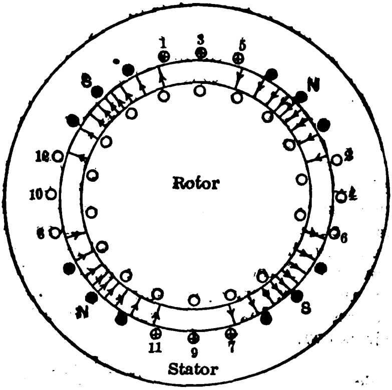

Fig. 1. Elementary Induction Motor

Poles of an Induction Motor. — In Fig. 1 is given a diagram of the primary winding of a two-phase induction motor. The small numbered circles represent the conductors forming the winding of one phase, the small black circles the conductors forming the winding of the second phase. The numbers opposite the circles give the order in which the current in phase 1 passes through the conductors, a cross indicating that the current goes down into the page and the open circles that the current is coming up.

The diagram is drawn to represent that instant at which the current in the second phase is zero. At this instant the distribution of flux in the air gap will be roughly as indicated by the lines with arrows on them; that is, the flux will leave the stator iron in the two regions marked N and enter it in the two regions marked S. Consequently, the current in the winding of phase 1, which consists of 4 bands or groups of conductors, will produce 4 polar regions, or 4 poles, on the stator. As will be shown below, the combined effect of the two phase currents in the two windings is merely to cause a rotation of these polar regions. The "number of poles" is always equal to the number of bands of conductors into which the total winding of each phase is divided. The bands of conductors forming one phase usually overlap the bands of conductors forming the other phase, there being then two or more conductors per slot.

Rotation of Magnetic Flux. — In Fig. 1 is shown the distribution of flux in the gap when the current in phase 2 is zero; the curve marked A in Fig. 2 represents this same state of affairs, the cylindrical surface of the stator here being bent out into a plane, and the ordinates of the curve giving the value of

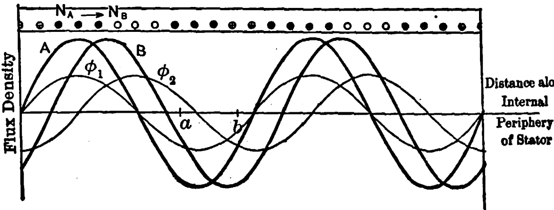

Fig. 2. Rotating Field

the flux density in the gap at each point of this surface. The flux distribution is not a smooth curve as shown, but approximates such a curve.

Next consider the case when the current in phase 1 has decreased to, say, 0.7 of its maximum value and the current in phase 2 has increased to 0.7 of its maximum value (this corresponds to ⅛ of a cycle). Then the flux distribution due to phase 1 remains in the same position as before but is reduced at each point of the gap to 0.7 of its maximum value, i.e., reduces to the curve marked ϕ_1. Similarly, the flux due to the current in phase 2 is similar in shape to the flux due to the current in phase 1, but its position is to the right of the latter by an amount equal to the width of one of the bands of conductors. The distribution of the flux due to the current in phase 2 is then as shown by the curve ϕ_2, the ordinates of which at the instant under consideration are 0.7 of their maximum values.

The resultant flux in the air gap at this instant is then the sum of the curves ϕ_1, and ϕ_2, namely the curve B. That is, the effect of the two fluxes due to the two phases is a resultant flux shifted forward, or moved around the gap, a distance equal to ⅛ the distance between successive north poles, but this resultant flux curve has the same shape and maximum value as before. This is strictly true only if the windings are distributed with absolute uniformity over the internal periphery of the stator. An extension of this analysis will show that the resultant flux remains constant in value at all times but travels around the air gap with a speed of

$$N = \frac{120f}{p} \text{ rev. per min.,}$$

where f is the frequency of the supply and p the number of poles.

This same result holds for a three-phase machine.

Synchronous Speed. — The speed of rotation of the air-gap flux, namely the speed N given by the above formula, is called "synchronous" speed. At light loads the speed of the rotor is very nearly equal to this speed.

Slip. — The slip of an induction motor is the ratio of the difference between the actual speed (N_1) of the rotor and synchronous speed (N) to the synchronous speed (N), i.e.,

$$s = \frac{N - N_1}{N}.$$

The slip may be expressed as a fraction or as a per cent. The slip at standstill is unity; at no load it is very nearly zero. An induction motor driven at a speed higher than its synchronous speed has a negative slip; such is the case in an induction generator.

Electromotive Forces in Secondary. — The electromotive forces in the secondary of a polyphase induction motor are induced by the rotation of the flux produced by the currents in the primary windings, just as the electromotive forces induced in the armature conductors of a generator are induced by the rotation of these conductors in the magnetic field set up by the field winding. In the generator only the conductors move, the field being stationary, but in the induction motor both the field and conductors move. In either case it is the *relative* motion of the field and conductors which determines the e.m.f. induced.

Let v be the linear speed at which the field moves, and let v_1 be the linear speed of the rotor conductors, and B the flux density at any particular conductor C at any instant. Then the e.m.f. induced in this conductor at this instant is $B(v - v_1)l = Blsv$, where s is the slip and l is the length of the conductor (*see also Electricity and Magnetism, Principles of*). The rotor electromotive force is therefore proportional to the slip. As the rotor turns, the conductor C moves slower than the rotating flux, and the state of affairs is just the same as if the flux remained at rest and the conductor moved through the field in the gap at a speed of $v - v_1 = sv$. Hence the electromotive force induced in each rotor conductor is alternating, since the flux which it cuts varies from a positive maximum to a negative maximum, and a consideration of the relative speed of the conductor and the flux will show that the frequency of this induced electromotive force is the frequency in the primary multiplied by the slip.

That is, the secondary electromotive force is proportional to the slip and has a frequency equal to the product of the slip by the frequency in the primary.

Secondary Current and Torque. — The current set up in each rotor conductor by this electromotive force will be practically in phase with this electromotive force, since the rotor conductors have but a small reactance, particularly when the rotor is revolving at a speed near synchronism. Hence the current in any chosen rotor conductor at any instant is proportional to the electromotive force in this conductor at that instant, which in turn is proportional to the flux density at this conductor at this instant. Since the force produced by a magnetic field on a conductor is equal to the product of the flux density by the current by the length of the conductor (*see Electricity and Magnetism, Principles of*), the force acting at any instant on any rotor conductor will then be equal to

$$f = Bli = Bl\left(\frac{Blsv}{r}\right) = \frac{B^2l^2sv}{r},$$

where r is the resistance of the conductor. Since the current and the flux density both change signs at the same time (being in phase) the direction of this force will always be in the same direction and will consequently drive the rotor against whatever opposing force may exist.

Not only is the force on each conductor always in the same direction, but the *total* force acting on *all* the conductors is practically constant for a given value of the slip. Consider any two rotor conductors which are a distance apart equal to ¼th the distance measured along the periphery of the rotor between successive north poles, for example, at a and b in Fig. 2. Then, assuming a sine-wave distribution of flux in the air gap, and calling B_m the maximum flux density, the flux density at a is $B_a = B_m \sin x$ and the flux density at b is $B_b = B_m \cos x$, where x is a function of the distance measured from some fixed point in the air gap. Then the total force on the two conductors at a and b is

$$\frac{l^2 s v B_m^2}{r}(\sin^2 x + \cos^2 x) = \frac{l^2 s v B_m^2}{r}$$

and is therefore constant, since B_m is a constant. Similarly for any other two conductors this same distance apart. Hence the total force on all the conductors is constant. On any practical machine the flux distribution is not an exact sine wave, and there is a slight pulsation in the total force, and therefore in the torque, but this pulsation is extremely small.

Magnetizing Current. — The currents set up in the secondary of an induction motor produce a rotating flux, which travels with the same speed with respect to the primary and in the same direction as the flux set up by the current in the primary, but the direction of this secondary flux at any point in the air gap is opposite to the direction of the primary flux. Hence the resultant flux when there is current in the secondary is equal to the difference of these two fluxes, and this difference remains practically constant irrespective of the secondary currents, just as the resultant flux in a transformer is practically independent of the secondary current. The primary current which would be necessary to produce this *resultant* flux is called the "magnetizing" current, and is very nearly equal to the current in the primary when the motor is running without load, in which case the current in the secondary is extremely small.

METHODS OF RATING. — The Standardization Rules of the A.I.E.E. up to 1914 recommended that the rating of an induction motor should be the load in horse-power which it will deliver continuously at the shaft with a maximum rise in temperature of any part not exceeding 50° C. by thermometer. In commercial practice three variations of this have been developed to suit different conditions, as noted below. See, however, the new ratings recommended in the proposed rules of 1914, given in the article on *Standardization Rules of the A.I.E.E.*

A-Rating. — For cases where there are no excessive overloads and where the load is fairly steady, it is customary to guarantee that the motor will operate continuously at its rated load with a maximum rise in temperature of 40° C., and that subsequently it will deliver a load 25 per cent greater than the rated for two hours with a maximum rise in temperature not exceeding 55° C.

B-Rating. — For cases where there are frequent overloads and for intermittent service, that is, a low load factor, it is customary to guarantee that a motor will deliver its rated load continuously with a rise in temperature not to exceed 35° C., and that it will deliver an overload of 50 per cent for two hours with a maximum rise in temperature not exceeding 55° C.

One-hour Rating. — Certain motors for special intermittent work, as for hoists, elevators, etc., are rated in accordance with the output they will give for one hour.

Starting and Break-down Torque. — In addition to the ability to carry its rated load without excessive heating and with reasonable constants, such as

efficiency, power factor and slip, it is advisable to make sure that the motor is able to start such loads as must be brought up to speed with the motor, as good starting ability in an induction motor involves certain complications and expenses. This subject is treated at length in the section below on *Methods of Starting*. Another important point is that the motor should be able to carry momentary overloads without "breaking down" as it is called, which means gradually decreasing in speed to a standstill when the load is excessive. To be sure of this qualification we must know the maximum output of the motor, which should be at least 50 per cent greater than the rated output.

VOLTAGE. — Motors may be wound for any voltage up to 13,000 but the great majority and all the small motors are wound for voltages of 110, 220 or 440 volts between lines.

FREQUENCY AND SPEED. — Induction motors may be built for any frequency. The higher frequencies are satisfactory in those cases where the load never exceeds normal conditions. Lower frequencies, such as 25, are more favorable where frequent overloads are met with or large starting torques are required.

The speed of the rotor of an induction motor at normal loads approaches within 5 to 10 per cent of the synchronous speed. The synchronous speed is fixed by the frequency of the system and the number of poles of the winding (*see above*) so that for a given frequency of the supply circuit there are only certain speeds available. Thus for 25 cycles we have

1500 for 2 poles;	500 for 6 poles;
750 for 4 poles;	375 for 8 poles, etc.

PHASE CONNECTIONS. — Two-phase or quarter-phase motors are usually wound with independent phase windings. Three-phase motors are connected in Y or Δ, depending upon the convenience of the designing engineer.

In a single-phase and two-phase motor the voltage and current per phase are the same as the voltage between lines and current in line; in a Y-connected three-phase motor the current per phase is equal to the line current, and the voltage per phase is equal to the line voltage divided by $\sqrt{3}$; in a Δ-connected three-phase motor the current per phase is equal to the line current divided by $\sqrt{3}$, and the voltage per phase is equal to the line voltage.

CURRENTS TAKEN BY MOTORS. — Let

P_0 = horse-power output;
I = current in each line;
ϵ = efficiency as a decimal fraction;
$\cos\phi$ = power factor as a decimal fraction;
E = voltage between lines (between one outside wire and the middle wire for three-wire two-phase line).

Then for

$$\text{Two phase: } I = \frac{373\,P_0}{\epsilon E\cos\phi};$$

$$\text{Three phase: } I = \frac{431\,P_0}{\epsilon E\cos\phi}.$$

Usual efficiencies and power factors at full rated load for polyphase motors are as follows:

POWER FACTORS AND EFFICIENCIES

Horse-power	25 cycles		60 cycles	
	Efficiency	Power factor	Efficiency	Power factor
1	0.79	0.78	0.78	0.78
5	0.85	0.88	0.82	0.88
20	0.88	0.91	0.84	0.91
50	0.90	0.92	0.87	0.92
100	0.905	0.925	0.89	0.92
200	0.91	0.925	0.905	0.92

DESIGN. — The methods of calculating two-phase and three-phase motors are practically the same. Most induction motors on single-phase circuits are made with polyphase windings, as the extra winding is necessary in starting.

The factors which must be considered in the design of an induction motor are the same as those considered for a synchronous generator with the addition of the power factor. It is desirable to have a high power factor but a high power factor requires a generous use of material, a small air gap, and a careful arrangement of windings. A high power factor at light load requires a small magnetizing current, and a high power factor at overloads requires a low value of leakage flux.

A small value of magnetizing current is obtained by using a small air gap and a large value of diameter per pole.

A low value of leakage flux is obtained by using a large value of diameter per pole and by subdividing the windings in a large number of slots.

Preliminary Choice of Main Dimensions. — In the discussion below the following symbols are employed:

E = volts per phase;
I = full-load current per phase;
D = diameter of armature, in inches;
L = length of armature, in inches;
p = number of poles;
f = frequency in cycles per second;
g = length of gap, in inches;
B = average flux density in gap, in lines per square inch;
ϕ = flux per pole, in maxwells;
S = turns in series per phase;
N = revolutions per minute;
α = quotient of no-load current divided by full-load current (ranges from 0.45 for a 1-horse-power motor to 0.25 for a 200-horse-power motor);
σ = ampere-conductors per inch of periphery. The values given in the article on *Generators, Alternating-Current*, also apply to the induction motor.
T = ratio of width of tooth at face to slot pitch (T varies from 0.6 to 0.7 for open slots and from 0.9 to 1.0 for overhung slots);
q = ampere-conductors per slot.

Diameter and Length of Armature. — The first problem in the design of an induction motor is the estimation of the proper diameter of armature. There are three methods of determining the proper value of this very important dimension:

(a.) Reference to machines already built, which shows that the diameter varies directly with the number of poles and inversely as the frequency. Thus for customary values of diameter in inches divided by the number of poles:

for 25 cycles, D/p = 5 to 6 inches;
60 cycles, D/p = 2.5 to 3 inches.

(b.) The peripheral speed, being a direct function of the diameter and speed, determines the diameter. As the value of the peripheral speed may vary from 3000 to 10,000 feet per minute, depending on the mechanical construction, this function is not very definite. For lack of more definite figures, 5000 feet per minute may be considered a good average figure for peripheral speed.

(c.) On account of the effect of the magnetizing current on the power factor it is desirable to limit the value of this current to a certain percentage of full-load current (*for values see p. 988*). To accomplish this there is a certain minimum limit to D and L which is expressed approximately in the equation

$$D^3L = \frac{28.7 \times 10^{12} fgk}{\alpha \sigma^2 N^2} \times \text{(Kv-a. rating)}.$$

k = ratio of the actual excitation current to the excitation current for the air gap; $k = 1.2$ for 60 cycles and $k = 1.4$ for 40 cycles.

This gives a relation between D and L. Assuming that for best economy L is equal to the pole pitch $\left(L = \frac{\pi D}{p}\right)$ a value for D is obtained. This formula also indicates the effect on the general design which would result from radical changes in any of the quantities.

The formula given for the preliminary calculation of dimensions of an alternating-current generator (*see article on Generators, Alternating-Current*) may also be used if proper values for T and L be selected.

Air Gap (g) varies in length according to the diameter, usual values being given in the accompanying table.

Diameter, inches	Air gap, inch
0 to 12	0.02 to 0.03
12 to 26	0.03 to 0.04
26 to 50	0.04 to 0.06
50 to 100	0.06 to 0.10
100 up	Diameter/1000

Average Flux Density in Gap (B). — The usual value of the average flux density in the air gap for 25 cycle machines is 30,000 lines per sq. in. and for 60 cycle machines is 25,000 lines per sq. in.

Conductors per Slot (c). — The "effective" number of conductors per slot is the number of conductors *in series* per slot, i.e., if each phase is made up of two windings in parallel, the two conductors of the two parallel windings are counted as one conductor. Hence the effective conductors per slot are

$$c = \frac{2S \times \text{(Number of phases)}}{\text{(Total number of slots)}}.$$

The permissible number of ampere conductors per slot (q) depends upon the permissible current density per square inch of copper, usual values of which are

Size of motor	Voltage	Amperes per sq. in.
Small	Low	3000
Small	High	2000
Large	Low	2000
Large	High	1600
Large	Above 6000	1000

Usual values of q are

Size of motor h.p.	Value of q
Up to 5	Up to 250
5 to 50	250 to 350
50 to 100	350 to 450
100 to 200	450 to 600
Greater	Up to 800

Number and Dimensions of Slots. — The number of slots is

$$\frac{\pi D\sigma}{q}.$$

The conductors should be arranged to give slots having a depth about four times the width, and the width of slot should be about ½ to ⅔ of the pitch of slots at the gap. Machines of small diameter will have slots smaller with respect to the pitch and machines of large diameter will have slots occupying more than ⅔ of the pitch.

The slots of one member at least (usually the rotor) should be overhung, i.e., partly closed at the opening. It is better if both members have partly closed slots, as this reduces the magnetizing current and improves the power factor, but it entails a more expensive method of winding.

The dimensions of the slots are determined by the size of conductors and amount of insulation. The allowance to be made is about as follows:

Type of slot	Voltage	Coil sides per slot	Allowance for insulation	
			Vertical	Horizontal
			in.	in.
Straight	500	2	0.30	0.04
Straight	2200	2	0.45	0.15
Straight	6000	2	0.65	0.25
Overhung	500	4	0.40	0.15
Overhung	2200	4	0.50	0.20

The depth of the slot is found by adding to the total depth of cotton-insulated copper the vertical dimension given in the table.

Turns in Series per Phase (S) may be calculated from the formula

$$S = \frac{\pi D \sigma}{2I \times (\text{number of phases})}$$

or from the formula

$$S = \frac{10^8 E}{4.44 \phi f k},$$

where ϕ is the flux per pole and is given by the formula

$$\phi = \frac{0.7 \pi BDL}{(\text{number of poles})}$$

and k is a constant depending on the wave form and winding distribution (*see next paragraph*). The value of S as obtained from these two formulas must check in the final design.

Flux per pole (ϕ). — The flux per pole is given by the formula

$$\phi = \frac{10^8 E}{4.44 f S k},$$

where k, called the distribution constant, has the values given in the following table, provided the flux distribution in the air gap is sinusoidal.

DISTRIBUTION CONSTANT k

Two phase					Three phase				
Slots per pole	Per cent winding pitch				Slots per pole	Per cent winding pitch			
	100	75	67	50		100	75	67	50
	k	k	k	k		k	k	k	k
2	1.00	....	....	0.71	3	1.00	....	0.87	....
4	0.93	0.85	....	0.66	6	0.97	....	0.84	0.69
6	0.91	....	0.79	0.64	9	0.96	....	0.83	0.68
8	0.905	0.84	....	0.64	12	0.96	0.89	0.83	0.68
12	0.90	0.836	0.78	0.63	18	0.958	0.885	0.83	0.68
Many	0.90	0.833	0.78	0.63	Many	0.958	0.885	0.83	0.68

Choice of Phase Connection. — The decision whether a motor shall be Δ or Y connected depends on such minor details of design as the convenience of arranging the conductors in the slots. For instance, if for 110 volts and Δ connection a desirable flux value and number of conductors would require 7 conductors per slot, a Y connection having 64 volts per phase and 4 conductors per slot could be substituted and would give a practical winding. 64 volts per phase, Y connected, gives 110 volts between lines.

Magnetic Circuit. — A tentative layout of the magnetic circuit is next made in the same manner as described in the article on *Generators, Alternating*.

Current. The values there given for usual values of the flux density also apply to the *maximum* instantaneous flux density in the magnetic circuit of an induction motor. The magnetic circuit must have such dimensions that the exciting current will not be too large, and the slots must be of sufficient size to accommodate conductors of necessary size (*see above*).

Maximum Efficiency and Power Factor. — Since induction motors frequently operate on an intermittent or variable load, it is desirable that the efficiency and power factor be high at fractional loads. It is therefore quite usual to design the motors so that the maximum efficiency comes at ¾ load and maximum power factor at less than full load. This is accomplished with regard to efficiency by making the core-loss and friction small (the core-loss is made small by using low flux densities) and with regard to power factor by making the magnetizing current small by using a small air gap.

PREDETERMINATION OF PERFORMANCE OF AN INDUCTION MOTOR FROM ITS DIMENSIONS. — From the above calculations a preliminary drawing of the motor to scale may be laid out. The next step is to calculate its performance, i.e., predetermine what will be the efficiency, the power factor, and the temperature rise in the various parts. Examples of specific design and tested performance are given below.

Calculation of Exciting Current. — The first step is the calculation of the exciting current. This current is practically constant at all loads, and is equal to the no load current, i.e., the current taken by the motor when it is running light. The exciting current has two components, the magnetizing current, which leads the induced voltage by 90° and a component in phase with the induced voltage, which supplies the core-loss and friction. The magnetizing current is much the larger component, and for preliminary calculations may be taken equal to the exciting current.

Magnetizing Current. — The magnetizing current is calculated by determining the flux density in each part of the magnetic circuit and the ampere turns required for each part. This is most easily done by means of the following tabulation:

MAGNETIC DENSITIES AND M.M.F.'S

(For dimensions refer to Fig. 3.)

Part	Flux per pole	Area	B_{max}	A.T. per inch	Length path	Total A.T.
Stator core.....	$\phi/2$	$h_1 \times l$	$1 \times B_{avg}$	....	$\frac{\pi D_1}{2 \times \text{poles}}$	....
Stator teeth....	ϕ	$r_1 \times l \times \frac{\text{slots}}{\text{poles}}$	$\frac{\pi}{2}$ $1.57 \times B_{avg}$	....	n_1	....
Air gap.........	ϕ	See below	$1.57 \times B_{avg}$	....	g	....
Rotor teeth....	ϕ	$r_2 \times l \times \frac{\text{slots}}{\text{poles}}$	$1.57 \times B_{avg}$	....	n_2	....
Rotor core.....	$\phi/2$	$h_2 \times l$	$1 \times B_{avg}$	....	$\frac{\pi D_2}{2 \times \text{poles}}$	....
					Total.....	....

Stator Core or Yoke. — The flux divides in the core, one-half going each way. The maximum and average* densities are practically the same and equal to ($\phi/2$ divided by the radial depth h_1 times the effective length l). The material is laminated steel of high permeability. The ampere turns per inch length of path are obtained from a magnetization curve of the steel, see *Magnetic Properties of Iron.* The length of path is indeterminate but closely approximates one-half of the pole pitch measured on the circle of diameter D_1. By multiplying the ampere turns per inch obtained from the magnetization curve by the length of path, the ampere turns required to send the flux through this path are obtained.

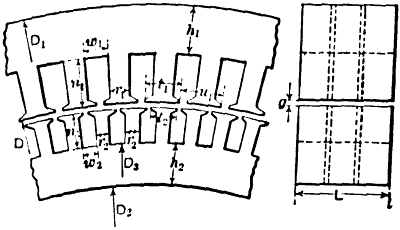

Fig. 3. Dimensions of Magnetic Circuit

Stator teeth. — The average density in the teeth is first obtained. The effective area of one tooth is the area one-third the distance from the face to the root of the tooth as shown at r_1. This gives the average magnetizing force rather than the average density. The total cross section of the path in the teeth is therefore $r_1 \times l \times$ (the number of teeth per pole). Due to the peaked or sinusoidal space distribution of the flux the maximum density in the teeth is 1.57 times the average density. The ampere turns required depend upon the maximum density. From the proper curve determine the ampere turns per inch necessary to establish this density, and by multiplying this quantity by the distance n_1 in inches, the ampere turns for the stator teeth are found.

Air Gap. — The flux is not uniformly distributed in the air gap, especially if the openings of the slots are fairly large. The flux passes through each tooth and spreads out from the iron when it leaves the teeth to cross the gap. The peripheries of the stator and rotor present unequal and dissimilar surfaces passing each other. The lesser of the two is the one that must be considered. The effective area of the air gap is

$$\frac{(t+g)\, l \times (\text{total number of slots})}{0.9\, p}$$

and the maximum density $= \dfrac{1.57 \times \phi}{\text{gap area}}$

(the $t+g$ allows for the spreading of the flux in one direction and $l/0.9$ allows for the spreading in the other direction).

The ampere turns per inch are $0.313\, B_{\max}$. The length of gap being known, the total ampere turns for the gap are found.

Rotor Teeth. — The calculation of the ampere turns for the rotor teeth follows the same method as the calculation for the stator teeth.

Rotor Core. — The same as for the stator core.

The effective value of the magnetizing current is then

$$I_m = \frac{(\text{Total ampere turns}) \times p}{2\sqrt{2}\, S} \text{ for three phases}$$

$$\text{and } I_m = \frac{(\text{Total ampere turns}) \times p}{\sqrt{2}\, S} \text{ for two phases}$$

* By average is here meant the average over the cross section of the maximum instantaneous value of the flux density, which, of course, alternates between fixed positive and negative values.

Resistance per Phase of Primary Winding. — The resistance to direct current, or ohmic resistance, is given by the formula

$$r_1 = \frac{0.0093\, S \times (\text{mean length of turn})}{12{,}000\, an},$$

where

S = turns in series per phase,
a = cross section of one conductor in sq. in.,
n = no. of conductors or circuits in parallel,

and 0.0093 is the resistance at 60° C. of a conductor 1000 feet long and 1 square inch cross section. The mean length of turn is approximately (see Fig. 3)

$$2L + 10\frac{D}{p} \times (\text{pitch as a fraction}).$$

Due to the eddy currents set up in the primary conductors by the total flux and to eddy currents set up in the core by the leakage flux, the "effective" resistance of the primary winding is about 15 per cent greater than the value calculated by the above formula.

Resistance per Phase of Secondary Winding. — In a wound rotor the resistance per phase is found in the same manner as the resistance per phase of the stator winding. The secondary resistance reduced to primary is then equal to $\left(\frac{\text{number prim. turns per phase}}{\text{number sec. turns per phase}}\right)^2 \times$ (actual effective sec. resistance).

The squirrel-cage rotor, in which each slot contains one bar and all bars are short-circuited at each end by a ring presents a more complicated problem. It may be solved as follows:

$$\text{Amp.-cond. per sec. slot} = \frac{\pi D \sigma}{(\text{number of sec. slots})}.$$

σ = amp.-cond. per inch for full-load current.

$$\text{Current density in sec. bars} = \frac{(\text{amp.-cond. per slot})}{(\text{area of one bar})}.$$

Watts lost in bars = 0.775×10^{-6} (vol. of bars) (amp. per sq. in.)^2.

Area of bars per pole = (area of one bar) (number of bars per pole).

$$\text{Current density in rings} = \frac{(\text{current density in bars})\ (\text{area of bars per pole})}{4\ (\text{area of ring})}.$$

Watts lost in rings = 0.775×10^{-6} (vol. of both rings) (density in rings)^2.

$$\text{Resistance of sec. in terms of primary} = \frac{\text{total loss}}{3\ (\text{full load prim. current})^2}.$$

Leakage Reactance. — When the motor is loaded the currents in the secondary set up a counter m.m.f. which causes part of the flux to pass along the air gap instead of into the secondary core. This flux does not interlink both members and is therefore a leakage or useless flux. It is proportional to the load currents and to the permeance of this path. As the greater portion of the path is in the air and is of high reluctance, therefore that part of the path in the iron may be neglected. The flux in both the primary and secondary must be calculated.

Referring to the diagram Fig. 4, the permeance of these two paths are

$$P_1 = \left[\frac{o_1}{3w_1} + \frac{2r_1}{w_1 + q_1} + \frac{p_1}{q_1} + \frac{t_1 - q_2}{6g} + 0.37\frac{l_{s1}}{L}\log_{10}\frac{1.5\, l_{s1}}{V_{s1}}\right]L,$$

$$P_2 = \left[\frac{o_2}{3w_2} + \frac{2r_2}{w_2 + q_2} + \frac{p_2}{q_2} + \frac{t_2 - q_1}{6g} + 0.37\frac{l_{s2}}{L}\log_{10}\frac{1.5\, l_{s2}}{V_{s2}}\right]L$$

where

g = length of gap in inches,
l_e = length of end connection at one end in inches,
V_e = perimeter of end connections of coils in inches.
L = total length of iron in inches.

In these formulas the subscript 1 refers to the primary and subscript 2 to the secondary. The first three terms give the slot reactance, the fourth term gives the "zigzag" or "tooth-tip" reactance, and the last term the reactance of the end connections.

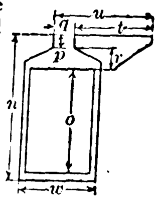

Fig. 4. Slot Dimensions

The primary reactance in ohms per phase is

$$x_1 = 3.2\, P_1 k c_1^2 s_1 \times 2\,\pi f 10^{-8}.$$

The secondary reactance in ohms per phase in terms of the primary turns is

$$x_2 = 3.2\, P_2 k c_2^2 s_2 \times 2\pi f 10^{-8} \left(\frac{c_1 s_1}{c_2 s_2}\right)^2,$$

where

c_1 and c_2 are the conductors in series per slot,
s_1 and s_2 are the slots in series per phase,
f = primary frequency,
k = winding distribution constant (*see above*).

Losses in Induction Motor. — The losses in an induction motor are

Core-loss;
Friction, bearing and windage;
Primary copper loss;
Secondary copper loss.

The first two of these are approximately constant for all loads and the last two vary as the square of the current per phase.

Core-loss. — The distribution of the magnetic flux in an induction motor is quite irregular both in the core and in the teeth. The losses are therefore greater and their calculation more involved than in machines having uniform density in each part. In the primary the frequency of the passage of the secondary teeth introduces pulsations which increase the losses. In the secondary the frequency, being proportional to the slip, is so low that the core-loss is negligible.

In order to avoid too lengthy and complex calculations use is made of empirical constants, by which the easily calculated losses are multiplied to derive the practical loss. The total loss consists of hysteresis and eddy loss in the primary core and primary teeth. The loss in watts per cubic inch for one cycle per second at any magnetic density is found by the curves given in the article on *Magnetic Properties of Iron*.

The losses are then calculated as follows:

Hysteresis Loss:

In primary core $= k_h C_1 f V_c$ watts,
In primary teeth $= k_h C_2 f V_t$ watts.

Eddy Loss:

In primary core $= k_e C_3 f^2 V_c$ watts,
In primary teeth $= k_e C_4 f^2 V_t$ watts,

where V = volume in cu. in., C = respective loss per cu. in. from curves, f = frequency, k_h = empirical constant, 1 to 1.5, k_e = empirical constant, 3 to 4.

The higher values of k_h and k_e are to be used where open slots are used and where the frequency of the passage of the secondary teeth past one primary tooth is high. The core-loss is the sum of all the above losses.

Friction and Windage Loss varies greatly with the style of motor and form of structure, bearings, etc. The loss is made up of bearing friction and wind friction. The latter may be large purposely, as the motor may be designed with fan blades in order to circulate the air for the purpose of keeping the motor cool by ventilation. While each manufacturer has a formula which will calculate the friction loss correctly for machines built according to a particular plan, no general formula can be assumed. The nearest approach to an estimate is obtained from the percentage given in the table below.

Primary and Secondary Copper Losses. — The calculation of the effective resistances of the primary and secondary windings is given above. The primary or secondary copper loss is equal to the product of the number of phases, the effective primary or secondary resistance per phase, and the square of the current per phase. The total copper loss is the sum of the primary and secondary copper losses.

Power Factor. — The power factor ($\cos\phi$) of an induction motor for a given current input (I) may be calculated roughly from the formula

$$\cos\phi = \cos(\alpha + \beta),$$

where $$\alpha = \sin^{-1}\left(\frac{I_m}{I}\right) \text{ and } \beta = \sin^{-1}\left(\frac{XI}{E}\right),$$

and I_m = magnetizing current per phase,
I = total current per phase,
$X = (x_1 + x_2)$ = total reactance per phase, the secondary reactance x_2 being reduced to the primary turns,
E = voltage per phase.

For a more exact formula for power factor and for the usual values of the power factor at rated load, see *below*.

Efficiency. — The efficiency (as a fraction) for a given current input is

$$\epsilon = 1 - \frac{F + C + m(r_1 + r_2)I^2}{mEI\cos\phi},$$

where F = friction loss, in watts; C = total core-loss, in watts; m = number of phases; r_1 = effective primary resistance per phase; r_2 = effective secondary resistance per phase reduced to primary; E = voltage per phase; I = current per phase; $\cos\phi$ = power factor.

The corresponding horse-power output is then

$$P_0 = \frac{\epsilon mEI\cos\phi}{746} \text{ horse-power.}$$

Usual values of the efficiency are given above in section on *Currents taken by Motors*. Usual values of the component losses for 60-cycle motors are given in the following table.

In 25-cycle motors the exciting current is usually greater than in 60-cycle motors and the IX drop less. Thus the power factor will be lower at light loads and higher at overloads than in 60-cycle motors.

Rating, h.p.	$\frac{Im}{I}$	$\frac{XI}{E}$	$\frac{\text{Friction loss}}{\text{Input}}$	$\frac{\text{Core-loss}}{\text{Input}}$	$\frac{r_1 I}{E}$	$\frac{r_2 I}{E}$
1	0.45	0.20	0.06	0.05	0.05	0.05
5	0.35	0.14	0.035	0.04	0.04	0.04
20	0.30	0.13	0.025	0.035	0.035	0.035
50	0.27	0.11	0.015	0.03	0.025	0.03
100	0.26	0.11	0.015	0.03	0.025	0.03
200	0.25	0.11	0.015	0.03	0.025	0.03

The efficiency of 60-cycle motors naturally tends to be higher than of 25-cycle motors. This quality is usually sacrificed by economizing in material and making the 60-cycle motors lighter and cheaper, but of about the same efficiency as the 25-cycle motors.

Slip and Speed. — The slip for any given current is approximately

$$s = \frac{r_2 I}{E},$$

where the symbols are defined in the preceding paragraph.

The synchronous speed is

$$N = \frac{120 f}{p} \text{ rev. per min.},$$

where f is the frequency of the supply and p the number of poles. The actual speed of the motor is then

$$N_1 = (1 - s)\, N.$$

Values of Other Characteristics. — The energy component of the exciting current is

$$I_e = \frac{(\text{Total core-loss}) + (\text{Total friction loss})}{mE},$$

where m is the number of phases and E the volts per phase.

The total exciting current per phase is then

$$I_{00} = \sqrt{I_e^2 + I_m^2},$$

where I_m is the magnetizing current per phase.

The impedance per phase at standstill ("short-circuit" impedance) is

$$Z = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2},$$

where r_1 and r_2 are the effective values of the primary and secondary resistances per phase, the latter being reduced to primary turns and x_1 and x_2 the primary and secondary reactances per phase, the latter being reduced to primary turns.

The current per phase at standstill ("short-circuit" current) is

$$I_s = \frac{E}{Z}.$$

The starting torque in pounds at 1-foot radius is

$$T_s = \frac{7.06\, m r_2 E^2}{N Z^2},$$

where m, r_2, E, and Z are as defined above, and N is the synchronous speed in revolutions per minute.

The slip at maximum output is

$$s_m = \frac{r_2}{r_1 + Z}.$$

The maximum output in watts is

$$P_m = \frac{0.5\, mE^2}{1.3\,(r_1 + r_2) + Z} \text{ watts.}$$

This should be from 1.5 to 3 times the rating of the motor. A 25-cycle motor usually has a greater maximum output or overload capacity than a 60-cycle motor.

Heating. — Since in most motors the primary member is subject to both a core-loss and a copper loss and is stationary, the heating of this member is very important. As the secondary contains only a copper loss and is usually revolving, its rise in temperature is usually much less than that of the primary.

The problem therefore consists of analyzing the flow of heat and drop in thermal potential in the primary as the energy lost in the windings flows to the iron of the core through the insulation in the slots and to the air around the projecting end connections. The core itself is maintained at a temperature above the air by the core-loss. It is therefore necessary to calculate first the rise in temperature of the iron of the core caused by the core-loss and that portion of the copper loss which is conducted to the core through the slot insulation. It is then necessary to calculate the rise in temperature of the copper above the iron and above the air around the end connections.

Since at times in every motor, when the core-loss is great compared with the copper loss, the iron may be hotter than the copper, it is necessary to distinguish between that portion of the power (P_1) which passes between copper and iron (or vice versa), and that portion (P_2) which passes from copper direct to the air. The analysis must take account of the fact that sometimes the heat due to core-loss passes to the copper and is dissipated by the end connections.

The method given here is based on the more exact and elaborate treatment given by Arnold in Vol. V of his treatise *Wechselstromtechnik*, but is simplified by assuming that the copper conductors have such a high heat conductivity that they have the same temperature throughout their length. The result is a value for the average temperature of the copper such as would be found by a resistance measurement. For a method of determining the maximum temperature in any spot the reader is referred to Arnold's treatise.

Temperature Rise of Iron of Core (T_i).—The heat which is dissipated by the core surface consists normally of the core-loss and that part of the primary copper loss occurring in the portion of the winding embedded in the slots. It is

$$H = \text{core-loss} + mI^2r_1\left(\frac{2L}{t}\right),$$

where
m = number of phases,
I = primary current per phase,
r_1 = effective resistance of primary per phase,
L = length of armature core between heads,
t = mean length of a primary turn.

The surface consists of the outer cylindrical surface of the core, the two annular surfaces at the ends, and the surfaces in the air ducts, see Fig. 3. Since the

surface in the air ducts is not as effective as the others, only half the air-duct surface is used.

The area is $A_i = \pi D_1 L + \frac{\pi}{4}(D_1^2 - D^2)(2 + d)$,

where D_1 = outside diameter of stator in inches,
D = inside diameter of stator in inches,
d = number of air ducts.

The rise in temperature of the iron of the core will then be $T_i = \frac{kH}{A_i}$, in degrees Cent., where k ranges from 30 for narrow machines to 50 for long machines.

Temperature Rise of Copper (T_c). — A part of the heat due to the copper loss flows from the copper to the iron through the slot insulation, due to the small difference in temperature between the copper and the iron, $T_c - T_i$, where T_c is the rise in temperature of the copper above the air. The power in watts so dissipated is

$$P_1 = A(T_c - T_i),$$

where

$$A = \frac{U_s L S_1}{d_1 k_1}$$

and U_s = perimeter of slot insulation,
S_1 = total number of slots,
d_1 = thickness of slot insulation,
k_1 = a constant, 200 to 250 (say, 210).

Sometimes T_i is greater than T_c and P_1 becomes negative, which means that some of the energy of the core-loss flows to the windings and is dissipated by the end windings.

Another portion, P_2, of the copper loss flows through the insulation of the end connections to the air. Here there are paths, insulation and air, in series, across which there is a drop in temperature of T_c°C. The flow of energy to the air is affected by the movement of the air, which, in turn, is a function of the peripheral speed V of the rotor. The value of P_2 is

$$P_2 = BT_c,$$

where

$$B = \frac{U_c l_c Z_1}{d_2 k_2 + k_3}$$

and U_c = perimeter of end connections, in inches,
l_c = length of end connections, in inches,
Z_1 = total number of coils,
d_2 = thickness of insulation on same, in inches,
k_2 = a constant, 400 to 500 (say, 430),
k_3 = resistance to flow of heat from insulation to air and is given by the formula,

$$k_3 = \frac{170}{1 + 0.015\,V};$$

where V = peripheral speed of rotor in feet per second.

The total copper loss is $P = P_1 + P_2$, whence

$$T_c = \frac{P + AT_i}{A + B}.$$

This is approximately the average difference in temperature between copper and air as it would be determined by a measurement of resistance.

TESTING OF INDUCTION MOTORS. — (*See also Standardization Rules of A.I.E.E.*) Induction motors may be given either an "input-output" test at load under working conditions, from which the efficiency and power factor may be determined, or the motor may be given a no-load excitation and no-load short-circuit test, from which all the characteristics may be calculated. The latter method requires very little power and is preferable in the case of large motors where it would be expensive to supply power and inconvenient to dissipate the energy.

Excitation Test. — In this test the machine is operated without load at constant frequency with the voltage varied through a range from 30 per cent above rated value down to as low a voltage as will cause the machine to rotate. The current in each phase is noted and by means of two wattmeters the power required is noted. This test is sometimes also made with the machine operating single phase for the purpose of checking the core-loss. The curves are plotted with voltage as abscissas and amperes and watts as ordinates. At very low voltages the core-loss is negligible and therefore the watts input may be taken as friction loss. Around normal voltage the real core-loss may be determined by subtracting from the input the small copper and the friction loss.

Short-circuit Impedance Test. — In this test the starting resistance, if there is any, is short-circuited and the armature is blocked to prevent rotation. A low voltage is applied to the primary until the ammeter in the primary circuit shows a current of from 1 to 1.5 times the full-load value. Two wattmeters are used to read the power input. As the leakage flux, and hence the reactance, varies with the relative position of the rotor and stator teeth, it is customary to take readings with the rotor in several positions. Sometimes the rotor is allowed to revolve very slowly at, say, two to three revolutions per minute. From this test the impedance (Z) of the machine is obtained by dividing the volts per phase by the current per phase; the combined effective resistance (R) of primary and secondary is found by dividing the watts input per phase by the square of the current per phase. This latter is the effective value of the resistance, since the watts input includes all losses due to eddy currents. From these values the total reactance (primary and secondary) of the motor is $X = \sqrt{Z^2 - R^2}$. With the results of the two preceding tests and the measured resistances of the two members, the characteristics of the motor may be calculated either by the Steinmetz Method or the Circle Diagram. (*See below under Performance, Calculation of.*)

Stationary Torque Test (Fig. 5). — This test may be made at the same time the impedance test is made and consists in the measurement of the torque of the motor by means of a brake arm and spring balance. When the current of the machine has been adjusted to a suitable value the brake arm (to which a known weight has been attached to overcome bearing friction) and the spring balance are allowed to move downward through a small arc, during which the spring balance will register a pull (P_1) equal to torque (T) plus the weight (W) minus the friction (F), that is, $P_1 = T + W - F$. The spring balance and brake arm are then raised against the torque through the same small arc and the spring balance will then register a pull (P_2) equal to the torque plus the weight plus the friction, that is, $P_2 = T + W + F$. From these two readings the friction can be eliminated

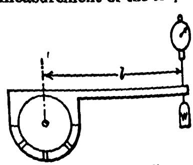

Fig. 5. Stationary Torque Test

and the actual torque of the armature on the shaft is determined. This should be done at two or three positions of the armature. The corrected torque of the machine is found by solving the two equations for T and multiplying T by the lever arm of the brake in feet; this gives the torque in pounds at 1-foot radius.

Load Test. — To make this test on a small machine a prony brake is required, while for a large machine a direct-current generator may be conveniently employed as a load. The induction motor and generator are direct-connected if possible, otherwise belted together. All the constants of the generator are determined, so that its losses under any condition may be calculated. The motor is then allowed to drive the generator, the rated voltage being impressed upon the motor, and the generator is loaded by means of a rheostat or a water-box so that any load may be obtained. The voltage across each phase of the motor, the current in each phase, the total watts input (by two meters), speed, and, if possible, slip (by a slipmeter, *see below*) are all read. Care must be taken that correct voltage and frequency are supplied to the motor. The load on the motor is increased step by step to the maximum output point, which is easily known, since when it is reached a decrease in speed is not accompanied by any increase in output of the motor. The motor is still stable at the maximum output condition, since maximum torque occurs at a lower speed than maximum output.

After the load run the direct-current generator is run as a motor with the same field strength as before, to determine the mechanical losses, first driving the induction motor at the proper speed, and then running alone at the same speed or speeds at which it ran in the load test. Knowing the no-load friction of the induction motor as previously determined in the *Excitation Test*, the increase in friction due to the belt and load is determined and half of it charged against the motor. Let

EI = the output of the direct-current generator in watts,
I^2R = the hot resistance loss in the direct-current armature,
CT = the counter torque or stray power losses in the direct-current generator plus one-half belt loss,
P_0 = watts input to induction motor.

$$\text{Then efficiency of the motor} = \frac{EI + I^2R + CT}{P_0}.$$

From these tests, curves may be plotted for the speed, efficiency, power factor current and torque of the induction motor for any horse-power output.

Use of Stroboscope to Measure Slip. — One type of slipmeter consists of a disk which is attached to the motor shaft and on which alternate sectors of black and white are shown, preferably as many black sectors as there are poles on the motor. If this rotating disk is illuminated by means of an arc light supplied with the frequency impressed on the primary of the motor, the disk will appear to rotate at a speed proportional to the difference between synchronous speed and actual running speed. The number of these revolutions for one minute, will be the slip in turns per minute, which may be translated into a fraction or percentage of synchronous speed.

Slipmeter. — Another type of slipmeter has two disks of insulating material mounted on the same frame, one carrying a wiping finger which makes contact with a button on the other disk. One of the disks is connected to a small synchronous motor which is driven from the same power source as the induction motor under test; the other disk is arranged to be readily attached to the shaft of the induction motor. The circuit of a miniature tungsten lamp is closed when the wiping finger and button are in contact. The number of flashes

of the lamp per minute gives the slip in revolutions of the induction motor behind the synchronous speed.

Heat Runs. — On machines of moderate size heat runs are advisable, but on large size machines heat runs are expensive. It is not always necessary to make a heat run in order to know whether the motor is properly designed, as the losses can be accurately calculated from the excitation and short-circuit tests, and the machine may be run without load but with losses equivalent in value to the losses at full load. The usual heat run consists in operating the machine at a certain output for a period from three to six hours, depending on the size, measuring the resistance before and after the run and taking temperatures by thermometer on the following parts after the run: primary winding, the iron surfaces in the air gap, secondary winding, bearings, frame.

A heat run which will indicate whether there is anything radically wrong with a motor consists in operating it for an hour or two with a voltage 15 per cent above normal, but without load.

Insulation Tests. — High-potential tests are made on the primary in the manner described under *Testing* in the article on *Generators, Alternating-Current*. The value of the high potential for the primary is chosen in accordance with its rated voltage from the *Standardization Rules of the A.I.E.E.* (q.v.). The potential applied to the secondary, however, has no relation to the rated voltage of the machine; as the working potential in the secondary is low, 1000 to 1500 volts is the usual range of testing potential for the secondary.

PERFORMANCE, CALCULATION OF. — The performance of an induction motor at any load may be determined directly from the load tests described above, or the performance at any load may be calculated from the excitation and short-circuit tests by either of the two methods given below. These methods are also applicable to the calculation of performance from the values of the constants calculated from the dimensions of the machine. The first method is given in detail by Steinmetz in his *Elements of Electrical Engineering*, and the Heyland Circle Diagram is given by McAllister in his *Alternating Current Motors*. The former is recommended where accuracy is desired and the latter (graphical) for the student desiring a general understanding of the relations.

Steinmetz Method. — This method is based upon the equivalent circuit of a transformer, as given in the article on *Transformers*. Let

E = impressed voltage per phase,

m = number of phases,

r_1, r_2, x_1, x_2 = resistance and reactance of primary and secondary respectively, per phase and reduced to terms of primary,

s = slip as a decimal fraction (assumed),

$$g = \text{primary no-load conductance} = \frac{\text{core-loss}}{mE^2},$$

$$b = \text{primary no-load susceptance} = \frac{I_m}{E}.$$

Assume a slip s and calculate

$$a_1 = \frac{sr_2}{s^2x_2^2 + r_2^2},$$

$$a_2 = \frac{s^2x_2}{s^2x_2^2 + r_2^2},$$

$$g_1 = g + a_1,$$

$$b_1 = b + a_2,$$

$$c_1 = 1 + r_1g_1 + x_1b_1,$$

$$c_2 = g_1x_1 - b_1r_1,$$

Then

Counter e.m.f. per phase	$e = \dfrac{E}{\sqrt{c_1^2 + c_2^2}}$,
Current per phase	$I = e\sqrt{g_1^2 + b_1^2}$,
Total volt-ampere input to motor	$P' = mEI$,
Watts input to motor	$P = me^2(g_1c_1 - b_1c_2)$,
Watts output of armature	$P_0' = me^2a_1(1 - s)$,
Watts output of pulley	$P_0 = P_0' -$ (friction in watts),
Efficiency	$\epsilon = \dfrac{P_0}{P}$,
Power factor	$\cos\phi = \dfrac{P}{P'}$.

Circle Diagram or Graphical Method (Figs. 6 and 7). — The method of the circle diagram is based on the fact that the electrical reactions in an induction motor (or transformer) may be represented without any great error by the reactions in two parallel inductive circuits as in Fig. 6. I_e and I_m represent the two components of the exciting current, which is assumed constant. R_m and X_m represent the total resistance and reactance (both assumed constant) of the motor and are in series with a variable resistance R_L representing the load.

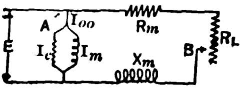

Fig. 6. Equivalent Circuits

The vector relations of the currents are as shown in Fig. 7, where

$OE =$ the impressed voltage per phase,
$OM =$ the current I_{oo} in A,
$MP =$ the variable current in B (not drawn).

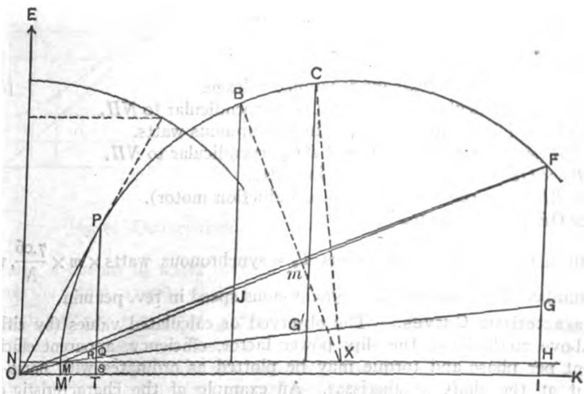

Fig. 7. Circle Diagram

Since the current represented by MP is equal to $\dfrac{E}{\sqrt{(R_m + R_L)^2 + X_m^2}}$, as R_L varies the point P will describe a circle through M, P and F, where $MF = \dfrac{E}{\sqrt{R_m^2 + X_m^2}}$. The total or resultant current will then be OP.

Heyland Circle Diagram (Fig. 7). — The circle diagram upon which the following discussion is based is a modification of Heyland's transformer, or induction motor diagram.

Let
OE = impressed voltage per phase.
OK be at 90° to OE.
OM = exciting current per phase, drawn in phase and magnitude.
OF = short circuit current per phase, drawn in proper phase and magnitude.
IF = energy component of OF.

Join M and F; then MF is the secondary short-circuit current in terms of primary circuit.
Bisect MF at m.
Draw mX perpendicular to MF at middle point, intersecting NH at X.
With X as center and either XM or XF as radius, draw the semicircle MCF. This is the locus of the primary current.
Since $OE \times IF$ = watts input at standstill, draw HG such that $OE \times HG$ = primary I^2R at standstill.
Then $OE \times GF$ = secondary I^2R at standstill.
Draw GM. The vertical distance between GM and NH at any point gives a current which if multiplied by OE gives the power loss in primary.
Choose any point P on circle; then OP = current per phase.
Then $\cos \measuredangle POE = \cos\phi$ = power factor.
MP (not drawn) = secondary current reduced to primary turns.

$PT \times OE$ = power input to primary, in watts.
$TS \times OE$ = no-load loss, in watts.
$QT \times OE$ = total motor loss.
$RT \times OE$ = total primary loss in watts.
$RS \times OE$ = primary copper loss, in watts.
$PR \times OE$ = secondary input, in watts.
$QR \times OE$ = secondary copper loss, in watts.
$QP \times OE$ = motor output, in watts.
$OM \div OP$ = per cent magnetizing current.
$M'T \div OP$ = per cent leakage reactance voltage.

These are all per phase

Draw XC perpendicular to MG and CG' perpendicular to NH.
Then $CG' \times OE$ = maximum torque in synchronous watts.
Draw XB perpendicular to MF and BJ perpendicular to NH.
Then $BJ \times OE$ = maximum output in watts.
$QR \div RP$ = per cent slip (in case of induction motor).
$OP \times OE$ = volt amperes input.

Torque in pounds at 1-foot radius T_s = synchronous watts $\times m \times \frac{7.06}{N}$, where m = number of phases and N = synchronous speed in rev. per min.

Characteristic Curves. — The observed or calculated values (by either of the above methods) of the slip, power factor, efficiency, apparent efficiency, current per phase and torque may be plotted as ordinates with horse-power output at the shaft as abscissas. An example of the characteristic curves thus plotted is shown in Fig. 8. Usual values of the various quantities for different sizes of motors at rated load are given above. The "power factor" shows the relation between the true power input of the machine and the apparent power, called the "volt-amperes." A poor power factor does not involve any greater registration of the watt-hour meter or cost of energy to operate the motor, but it does involve poor regulation of voltage in the system as a whole and larger capacity of wiring, transformers, etc. The "apparent efficiency" is equal to the product of the power factor and efficiency, or is equal

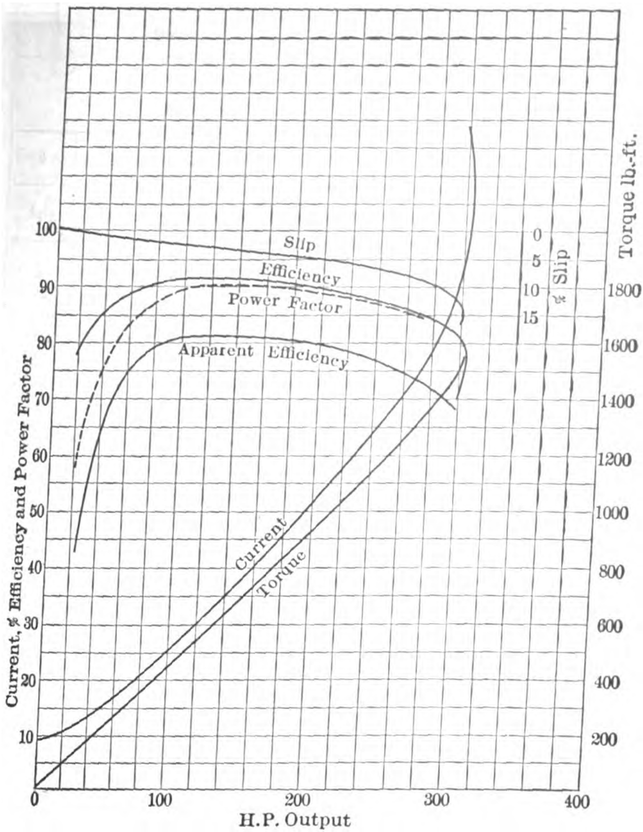

Fig. 8. Characteristic Curves of an Induction Motor

to the ratio of output in watts divided by input in volt-amperes. Its value determines the actual capacity of the lines and transformers supplying the motor.

EXAMPLES OF DESIGN AND PERFORMANCE. — In the accompanying tables are given the essential data for both mechanical and electrical features of six three-phase induction motors. The list of items will be found useful as a guide in collecting data on various machines. Performance data are deduced from tests.

METHODS OF STARTING. — In order to start an induction motor of any size without injurious heating either a resistance must be connected in the secondary circuit or the voltage impressed on the primary must be reduced. The two general methods of starting induction motors are known as "Potential Control" and "Rheostatic Control." The same methods are used for speed control (*see below*).

Starting by "Potential Control" Method (Fig. 9). — This method consists of reducing and regulating the voltage impressed on the primary, usually by means of a starting compensator or auto-transformer which provides one or two fractional voltages. In order to make use of this method the secondary must be of higher resistance than with other methods of starting. For this reason and for the reason that there is no need of making any change in the windings, a squirrel-cage rotor winding is customarily used with this method of starting. This winding is made up of one bar per slot, and all bars are connected at both ends to rings. To start the motor the primary is connected to taps on the compensator which give a voltage of from ½ to ⅔ the rated voltage if it is a small motor, and ⅓ to ½ if it is a large motor. A small motor may be brought up to full speed on this voltage but a large motor may require an intermediate step. The connections are shown in Fig. 9. It is customary to adjust the motor resistance and starting voltages to give the relations in the accompanying table.

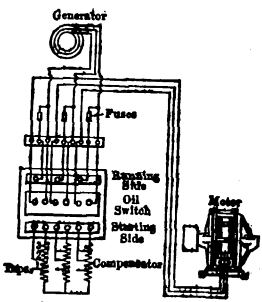

Fig. 9. Potential Control

Voltage on Motor, per cent	Current in line, per cent	Starting torque, per cent
33	75	22
50	175	50
66	300	88
100	700	200

Starting by "Rheostatic Control" Method (Fig. 10). — Better apparent torque efficiency, that is to say, more torque for a given current, is obtained by inserting in the secondary circuit a much greater resistance than can be left permanently in circuit. This is accomplished by having a special starting resistance connected in series with the armature winding and a switch for short-circuiting the resistance either step by step or as a whole, as the motor speeds up. There are two practical methods of doing this:

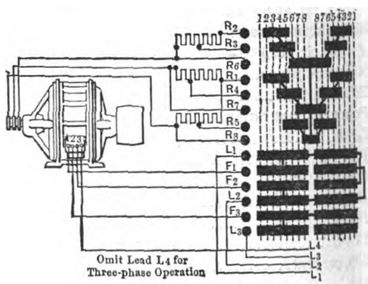

Fig. 10. Rheostatic Control

The first is intended to be used only when the torque required at starting is not very great, in which case the starting resistance may be small and located inside the armature spider. The switch lever is so arranged that the resistance can be short-circuited in steps while the armature is revolving. This obviates the need of collector rings and external connections.

The second method consists in bringing the three terminals of the secondary winding to collector rings. From brushes bearing on these rings conductors lead to external resistances with steps or taps so that the resistance may be short-circuited gradually. This scheme is used where a large starting torque (greater than full load torque) is required. It may be used also for speed control as shown in Fig. 12.

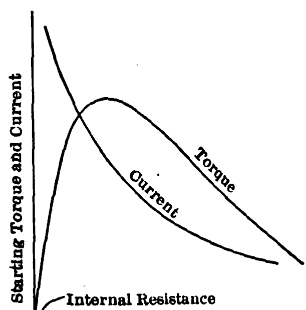

Fig. 11. Starting Resistance, Torque and Current

The proper value of resistance per phase in the secondary is determined by the relation

Torque in pounds at 1 foot =

$$\frac{E^2 r_x}{Z^2} \times \frac{7.06\, m}{\text{r.p.m.}} = \frac{7.06\, m r_x E^2}{N Z^2},$$

where

E = primary voltage per phase,

r_x = total secondary resistance per phase in terms of primary,

$Z = \sqrt{(r_1 + r_x)^2 + X^2}$, where r_1 is the resistance per phase of primary and X the total reactance per phase of both primary and secondary,

m = number of phases,

N = synchronous speed in revolutions per minute.

The relation between starting torque and total resistance of the secondary is shown by the curve in Fig. 11.

SPEED CONTROL OF INDUCTION MOTORS. — (*See also Hoists, Electric.*) The speed of an induction motor may be controlled in five ways:

(a) By varying the potential applied to the primary of motor having a suitable permanent resistance in the secondary.

(b) By varying the resistance in the secondary circuit.

(c) By changing the connections of the primary winding in a manner to change the number of poles.

(d) By varying the frequency of the applied voltage.

(e) By connecting the secondary of one motor to the primary of another, called the "concatenation" method of control.

Potential Control of Speed. — This method is an elaboration of the potential-control method of starting. A suitable resistance or auto-transformer reduces the line voltage to the fractional value desired. In this reduction the energy loss is only about 5 per cent of the amount transformed. The induction motor should have a very large resistance in the secondary, which is preferably of the squirrel-cage type. This resistance gives the motor a speed characteristic such that its full-load speed is some 10 per cent less than that of a normal motor. As the load is increased the speed may fall to about 30 per cent of the no-load value without the motor breaking down or falling out of step, which in the normal motor usually takes place at about 80 per cent of the full-load speed. This motor is not stable in speed as each slight change in the load will cause a change in the speed more or less inversely proportional to the load. The advantages of this method of control are the simplicity of the connections and devices. The disadvantages are the greatly increased heating in the motor itself with the decreased speed. Thus the motor must be larger than if other speed-control methods are used. The table given below shows the efficiencies obtained.

Rheostatic Control of Speed. — With this method (an elaboration of the method of the same name for starting) the secondary or rotor must have a definite winding (which costs more than the squirrel-cage winding used in the preceding method) with slip rings and brushes to lead out the current. The friction and resistance losses due to these brushes decrease the efficiency of the motor a slight amount. The action of this method is based on the principle that in an induction motor the drop in speed for any given torque is proportional to the resistance of the secondary circuit.

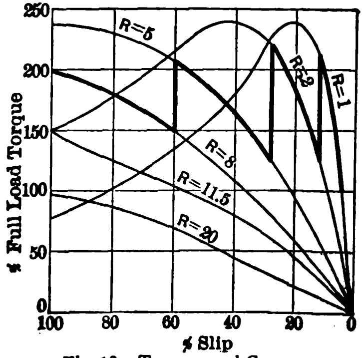

Fig. 12. Torque-speed Curves

Assuming a motor which has at full speed a net resistance of the secondary proper of 1 ohm, the speed-torque curve would be as shown for $R = 1$ in Fig. 12. This motor would have a slip of 5 per cent for full-load torque and of 25 per cent

for maximum torque, a torque at starting of 80 per cent of full-load torque and a very large starting current. If by some means this resistance is doubled the speed-torque curve would be as shown for $R = 2$, which shows a slip of 10 per cent for full-load torque and of 50 per cent for maximum torque. For $R = 5$, $R = 8$, etc., there would be other speed curves. By starting with a resistance of 8 ohms a torque of about 200 per cent of full-load torque would be obtained at starting with about twice full-load current. By allowing the motor to follow this curve until the torque has dropped to the full-load value, the motor would reach 60 per cent of synchronous speed, or 40 per cent slip. Then by reducing the resistance in steps the torque and speed would follow the heavy zigzag line until the motor reached full speed.

With this method of control the torque per ampere remains practically constant as in a shunt motor regulated by resistance in the armature circuit. The efficiency varies directly with the speed as shown in the table below.

The advantages of this method are the higher efficiency and particularly the smaller losses in the motor itself. The losses are in the rheostat. The disadvantages are the necessity of collector rings, brushes, controllers, etc. The motor is not stable at any fractional speed but the speed will change with every change of load.

Change of Poles to Control Speed. — By a proper design of the windings an induction motor may be made to operate with either 4 or 8 poles, 6 or 12 poles, or even 4 or 6 poles or 6 or 8 poles. This is accomplished by a throw-over switch to which taps from the windings are brought. In this arrangement the pitch of the primary winding must be made a compromise between the proper value for the different numbers of poles, and therefore the constants of the motor are not as good as those of a standard motor. It is also necessary to use a squirrel-cage armature, since this is suitable for any number of poles without change of connections. This type of motor operates advantageously only at the two speeds corresponding to the two arrangements of poles and is stable at each of these speeds. If a wider range is desired the potential-control scheme may be combined with it. The speeds and efficiencies with this scheme of control are given in the following table. At half-speed the efficiency is almost double that obtained with the other methods, but the losses in the motor are greater than with the rheostatic control.

COMPARISON OF METHODS OF SPEED CONTROL

(For constant torque equal to torque at full load)

Nominal speed	Potential			Rheostatic			Change of poles		
	Speed	Volts	Eff.	Speed	Volts	Eff.	Speed	Volts	Eff.
No load	1.00	100	..	1.00	100	..	1.00	100	..
Full speed	0.89	100	81	0.96	100	86	0.96	100	86
Three-quarter speed	0.67	66	59	0.72	100	65	....	...	..
Half speed	0.45	57	37	0.48	100	43	0.48	100	74
Quarter speed	0.22	56	17	0.24	100	22	....	...	..

Change of Frequency Method of Control. — The speed of an induction motor at any load varies directly with the frequency of the supply circuit. If two circuits from two alternators of different frequencies are provided the motors may be connected to one circuit for one speed and to the other circuit

for another speed. This method of speed control requires as many separate generators and circuits as the number of speeds desired. It is, therefore, costly and not widely used.

Concatenation Control or Cascade Control. — If two motors have definite windings in both the primary and secondary and are rigidly connected to a common shaft, they may be operated at a fractional speed corresponding to a number of poles equal to the sum of the number of poles on the two motors. With the concatenation control the primary (stator) of motor No. 1 is connected to the supply circuit, the secondary (rotor) of No. 1 is connected to the primary (rotor) of No. 2, and the secondary (stator) of No. 2 is connected to a resistance which is eventually short-circuited. When the two motors have the same number of poles, which is the usual commercial condition, motor No. 1 transforms half the power into mechanical power at the shaft at *half speed* and the remainder into electrical power at half frequency. Motor No. 2 receives this electrical power and transforms it into mechanical power at this same speed. If the number of poles is different, the speed in r.p.m. of the combination is

$$N = \frac{120f}{p_1 + p_2}.$$

These simple relations are exact only on the assumption of no losses and the rotor of No. 2 short-circuited.

The objections to this method of control are that the first motor has to carry the magnetizing current of both motors, thus having a low power factor. The first motor must receive the power for both motors; therefore, it must be the larger of the two and specially designed or there is an inefficient use of material in the second motor. If the two motors are alike (the usual commercial condition) the torque of the two motors in concatenation is not as great as that of the two motors in parallel.

The efficiency at fractional speed is, however, better than with the rheostatic method of control. Only two "free-running" speeds are available with two motors having the same number of poles. This scheme has been adopted frequently for the speed regulation of induction motors used on electric locomotives in foreign countries. In such applications it is frequently the custom to allow one motor to be idle at the higher speed.

INSTALLATION AND ERECTION. — Induction motors are usually built, even in large sizes, as a unit including the bearings, which are usually a part of the end frame of the motor proper. They may be either direct-connected or belted to their load, but the latter method is more general, since each induction motor can only be built for a certain definite speed corresponding to a certain number of poles. The smaller motors need no foundation, and in fact are frequently attached to the wall or to the ceiling, the bearings and end shield being made in such a manner that they may be turned through 90 degrees or 180 degrees so that the oil rings will operate properly under these conditions. In most motors reasonable ventilation, free from dust and dirt, must be available. For certain applications such as cement mills or mines, the motors are built totally inclosed and may then be even submerged in water. In this case, of course, a motor of a given rating is larger and more expensive than one of the open type.

OPERATION. — Small motors are designed to start merely by closing the main switch. With larger motors if the starting switch is at the proper position, potential may be applied to the motor and the starting resistance gradually cut out by moving the switch.

Induction motors are very sensitive to variation in the impressed voltage. A decrease in impressed voltage from 100 to 80 would cause the maximum

output and maximum starting torque to decrease from 100 to 64 and roughly would cause a proportional increase in the heating for a given load.

Unequal voltages in the different phases also cause a decrease in the maximum output and an increase in the heating for any given output. An unbalancing of 25 per cent in voltage would double the heating effect at full load, i.e., would give the same heating as an overload of 50 per cent.

Care in Starting. — Before starting the motor for the first time it is desirable to make sure that the starting device is in operating condition and in the proper position, in order that the motor should not become injuriously heated. Attention should be paid to having the wiring so proportioned as to carry the starting current without an excessive drop in voltage (*see above*).

Faults. — Some of the more common faults occurring in induction motors, together with their signs and remedies, are the following.

Secondary Open-circuited. — The motor will not start and will not take a current greater than the exciting current. The cause is probably due to the starting resistance not being connected in.

One Phase of Secondary Open-circuited. — The motor has a tendency to remain at half synchronous speed although the current is apparently normal. If the armature is blocked it will be found that the current in the three phases will be unbalanced.

One Phase of Primary Open. — The motor will not start and the current will be unbalanced.

One Phase of Primary Reversed. — The currents in the primary will be very much unbalanced when the motor is running and the starting torque will be very slight.

Short-circuited Coil in Primary. — There will be humming when potential is applied to the motor and excessive local heating around the short-circuited coil.

Vibration. — Vibration due to mechanical unbalancing is chiefly noticeable at high speeds and particularly in high-speed machines. If the vibration is due to magnetic unbalancing it is probably caused by inequality in the air gap at different portions of the circumference and with different positions of the armature. This may be detected by measuring the air gap with taper wedges at various points around the circumference, first with the armature in one position and then in several other positions.

SPECIFICATIONS FOR INDUCTION MOTORS.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Principal Characteristics and Conditions of Service. — Use to which motor is to be put; kind of load and method of drive. Voltage and number of phases. Rating, horse-power. Frequency and speed.

Style and Description; Details of Construction. — Whether to be open, semi-inclosed or inclosed. Requirements regarding pulley or length of shaft. Whether rails are required. Method of starting; compensator, external resistance or internal resistance; whether motor is to be run at speeds other than full speed. Whether the starting devices are to be supplied.

Performance and Tests. — (*See Standardization Rules of the A.I.E.E.*). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. Starting torque with full-load current, pound-feet. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation.

* W. A. Del Mar.

WEIGHT AND COST. — The weight and cost of an induction motor vary with the type of its armature winding and the character of its mechanical frame and housing, as well as with the speed, frequency and voltage.

The curves in Figs. 13 and 14 give an idea of the weights and costs of a line of 25-cycle and 60-cycle motors respectively, having squirrel-cage rotors (the simplest and least expensive type) and with the simplest form of mechanical frame. They therefore represent minimum values.

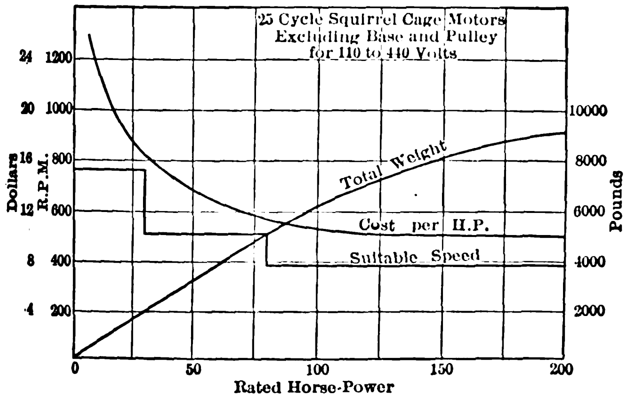

Fig. 13. Weight, Cost and Suitable Speed of 25-cycle Induction Motor

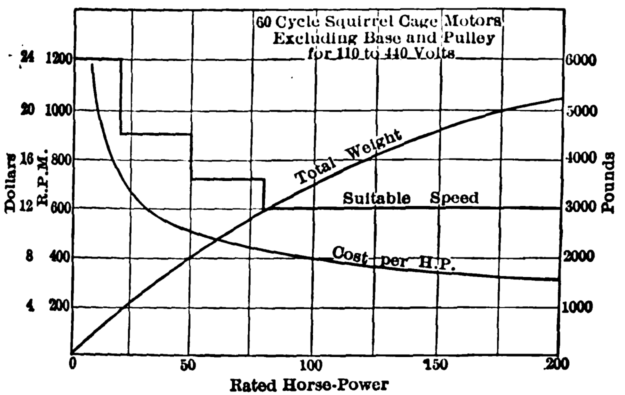

Fig. 14. Weight, Cost and Suitable Speed of 60-cycle Induction Motor

[W. I. SLICHTER.]

MOTORS, SINGLE-PHASE INDUCTION. — (*See also Motors, Polyphase Induction; Motors, A-C. Commutator*). A two- or three-phase induction motor may be operated as a single-phase machine after it is brought up to speed. Under these conditions it operates at a lower efficiency, lower power factor and with a lower maximum output than it would have as a polyphase motor. The slip for a given output is less in a single-phase motor than in a polyphase motor.

Load and Voltage Rating. — On account of the poorer operating characteristics and particularly on account of the lower maximum output or maximum torque, it is necessary to rate the motor at a lower capacity. When a three-phase motor is operated single-phase with the same voltage between lines, its maximum output will be approximately 40 per cent of the three-phase maximum output.

For best conditions, such as best distribution of losses and ratio of rated to maximum output, it is customary to use a three-phase motor, to reduce the rated output of the motor and to increase the rated terminal voltage in a definite ratio. Thus, if P be the rated output, in watts, of a given motor when operating on a three-phase circuit having a voltage between lines equal to E, then it would be advisable to operate the motor single-phase with a voltage between lines equal to $1.3\ E$, and to assign the motor a rating of from $0.67\ P$ to $0.75\ P$.

This will result in a distribution of losses in the motor quite similar to that which obtains during three-phase operation. The maximum output as a single-phase motor (at the higher voltage) will be about 67 per cent of the maximum output of the three-phase motor. The efficiency and power factor will be reasonable.

In case the voltage of the single-phase supply circuit must be the same, the winding of the motor is changed to give about 75 per cent as many turns in series per phase as for normal three-phase operation.

Exciting Current and Power Factor. — At a given voltage between terminals the volt-amperes input at no load for excitation are practically the same for single-phase and polyphase operation. Thus the no-load current of a single-phase motor is considerably greater than when operating polyphase. The increase in the applied voltage or the decrease in the number of turns makes a still greater increase in the magnetizing current. Thus the power factor of a single-phase motor is very poor at light loads and not very good at rated load.

CALCULATION OF PERFORMANCES. — To predetermine the characteristics of a single-phase motor it is calculated as a three-phase motor for the same voltage between lines as the single-phase circuit. The magnetizing current, core-loss, resistance per phase, and reactance per phase are all calculated as usual. The motor primary may be connected either delta or Y, but for purposes of calculation it is desirable to pro-rate the constants of a Y-connected motor on the assumption that it is delta connected.

To pro-rate the resistance and reactance per phase of primary and secondary, multiply the values for a Y-connection by 3 to obtain the values for the equivalent delta constants. The voltage per phase is presumed to increase in the ratio 1 to 1.73, while the voltage between lines remains the same.

The magnetizing current and the core-loss current are found by dividing the 3-phase values by 1.73.

The single-phase magnetizing current is found by dividing the volt-amperes excitation for three-phase conditions by the single-phase voltage. The core-loss in watts remains practically the same single-phase and the energy component of the single-phase exciting current is equal to core-loss watts divided by rated voltage.

The resistance and reactance of the primary of a single-phase motor are taken the same as the equivalent delta values per phase.

The resistance and reactance of the secondary of a single-phase motor are taken as ⅓ of the three-phase equivalent delta values.

These values are then substituted in the formulæ of the Steinmetz method (*see Motors, Polyphase Induction*) and the characteristics calculated for several assumed values of slip. The only difference in calculation is that the torque in synchronous watts is

$$T = e^2 a_1 (1 - s)$$

and the output of the armature is

$$P = e^2 a_1 (1 - s)^2.$$

It is of course understood that in a single-phase motor the output calculated for one phase is also the total output of the motor.

METHODS OF STARTING. — A single-phase motor has no torque at standstill. It must be started by some device such as a phase-splitting device. It may be started in either direction and as soon as it starts to rotate a slight torque develops which increases with the speed. When this torque has reached a great enough value to overcome the friction and inertia the special starting apparatus may be disconnected and the motor will continue to accelerate to its proper speed.

Starting of Small Motors.— Small motors may be started without auxiliary electric circuits by giving the armature a spin by hand, after which (if there is no load) they will accelerate. Certain small motors are designed with a loose pulley which is clutched at a predetermined speed of the armature by means of a centrifugal governor. These motors are provided with "shading coils" or a small external phase-splitting device, to give them just enough starting torque to overcome their own friction.

Starting of Large Motors. — A phase-splitting device is generally used; either a reactor and resistor or a condenser and resistor may be employed. Commutator devices are also used.

Use of Reactance Coil and Resistor. — The connections employed are shown in Fig. 1. This device consists of a resistance and a reactance connected so as to advance the phase of the e.m.f. impressed on one circuit of the motor and retard the phase of the e.m.f. on another circuit, while the line voltage is impressed on the third winding. This may be accomplished

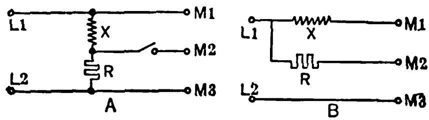

Fig. 1.

either by connecting the resistance and reactance across the line terminals and in multiple with the motor windings as shown in Fig. 1 A, or by connecting the resistance and reactance in series with the respective windings as shown in Fig. 1 B.

In these figures L_1 and L_2 represent line terminals, R is the resistance coil, X the reactance coil and M_1, M_2 and M_3 the three motor terminals. The former method gives a greater starting torque but takes a greater current in proportion to the torque. The latter method is more efficient. The motor must have sufficient resistance in its secondary circuit to give good starting characteristics as a three-phase motor.

The principle of this device is that the voltages between the outside terminals and the middle point are out of phase with each other and form a somewhat

flattened vector triangle similar to that of an unbalanced three-phase system. The ratio of the starting torque obtained with such a device to the normal starting torque with balanced three-phase voltages is the same as the ratio of the altitude of the triangle of vector voltages to the altitude of the equilateral triangle. Thus in Fig. 2 the ratio of altitudes is $30/95 = 0.316$; thus the single-phase starting torque would be 31.6 per cent of the three-phase starting torque.

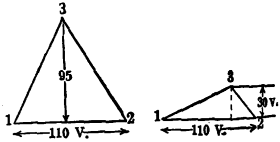

Fig. 2.

Use of Condenser and Resistor. — If a condenser of the proper capacity is substituted for the resistance the starting torque will be increased and the efficiency improved, but this is much more expensive and frequently involves the addition of a transformer across the condenser.

Use of Commutator. — Another method of starting single-phase motors involves the use of a commutator which permits the motor to start as a repulsion motor (which has good starting qualities; see *Motors, A-C. Commutator*), and after the motor has reached a considerable speed the brushes are removed from the commutator and a short-circuited squirrel-cage winding comes into play.

[W. I. SLICHTER.]

MOTORS, SYNCHRONOUS.—(*See also Alternating Currents; Generators, Alternating Current; Motors, Industrial Applications of; Motors, Polyphase Induction.*) Any alternator will operate as a motor. If two synchronous alternators are connected in parallel to bus-bars supplying a load, and the driving power be removed from one prime mover, the alternator connected to this prime mover will continue to run at the same speed as before, taking power from the other alternator and driving its own prime mover or other apparatus coupled to it; i.e., this alternator acts as motor. The speed of such a motor depends solely upon the speed of the generator or generators supplying electric energy to it; it is therefore said to run in "synchronism" with the source of supply and is called a synchronous motor. The synchronous speed of a synchronous motor having p poles, when supplied with a current of a frequency of f cycles per second, is

$$N = \frac{120f}{p} \qquad \text{rev. per min.}$$

If the load on such a motor increases the speed will not decrease, unless the load reaches such an excessive value that the maximum output or "pull-out torque" is reached, when the motor will drop out of step and come to rest, while the current taken will increase to short-circuit value and the torque decrease to a negligible value.

Differences between an Alternator and Synchronous Motor. — The difference in construction between an alternator and a synchronous motor is that the latter has placed in the face of the field poles, a squirrel-cage winding, which is intended to give good starting torque and to prevent hunting while running. A synchronous motor usually operates better with a higher value of armature reaction than that of a well-designed generator of the same kilowatt rating. This increase in armature reaction is usually obtained in practice by operating the machine as a motor at lower voltage than that for which it would be operated as a generator. Thus a standard 2300-volt generator will operate very satisfactorily as a motor at 2080 volts, and as these are the natural values of the generated and delivered voltages, this characteristic of the synchronous motor fits in very well with customary distribution practice. Thus a standard generator may have a squirrel-cage winding added to its poles and become a good synchronous motor.

Field Excitation. — Synchronous motors always require direct current for field excitation and if a suitable d-c. source is not available an exciter must be provided.

Number of Phases. — Synchronous motors may be single, two or three phase. The single-phase motor is not self-starting and has a considerably lower efficiency than the polyphase motor. It is also more liable to hunt (*see below*) and be unstable, and is therefore far less desirable than a polyphase motor. The two-phase and three-phase motors are very similar in all their characteristics. There is a slight economy in the three-phase over the two-phase motor as there is in the three-phase over the two-phase generator (q.v.).

Terminal Voltage. — Since synchronous motors are usually built with a revolving field and a stationary armature, it is possible to insulate the armature winding for voltages as high as 13,000 and thus obviate the need of transformers in many cases.

Advantages and Disadvantages of Synchronous Motors. — The advantages of synchronous motors as compared to induction motors are: higher efficiency, higher power factor, power factor may be controlled, constant speed,

high voltage, lower cost. The disadvantages are: need of an exciter, will not start under load, possibility of hunting.

Relations of Voltage and Current. — The relations between line voltage and phase voltage are the same as in a-c. generators (q.v.). The current in each line of a three-phase motor is

$$I = \frac{746\,P}{\sqrt{3}\,\epsilon\,E\cos\theta},$$

where

P = horse-power output,
E = voltage between lines,
ϵ = efficiency at load assumed,
$\cos\theta$ = power factor (may be unity).

Usual values for efficiency are about the same as for a-c. generators (q.v.).

APPLICATIONS. — In order to transform from alternating to direct current, or from one kind of alternating current to another differing in frequency, potential or phase relation, motor-generator sets, consisting of a synchronous motor direct connected to one or more generators, are often employed. By this means the potential of the secondary or distribution circuit is independent of the variation in potential of the primary circuit supplying power to the motor. In certain cases it is desired to take power from a 25-cycle circuit and supply power at 60 cycles for lighting purposes. Here a synchronous motor-generator set would be used. Such a set is frequently called a "frequency changer" (*see Motor Generators*). In some applications of electric drive by induction motors one synchronous motor is installed for the purpose of making it take leading current in order to neutralize the lagging current taken by the induction motors. This effect is produced by over-exciting the fields of the synchronous motor. The motor may be used to drive any machinery that does not require much starting torque. Such a motor is called a "rotary phase modifier" or "rotary condenser," see also below.

GENERAL PRINCIPLES. — In any synchronous generator or motor when a current flows in the armature there is a loss of voltage proportional to IZ_0, where I is the current and Z_0 is a hypothetical quantity called the synchronous impedance, which includes the effect of the resistance, the leakage reactance and the demagnetizing effect of the armature current. This quantity is obtained by the synchronous impedance test (*see below*) and is expressed in complex quantities as $Z_0 = r + jx_0$ and in algebra $Z_0^2 = r^2 + x_0^2$ where r is the effective resistance per phase and x_0 is the synchronous reactance per phase. IZ_0 is therefore the drop in voltage per phase in the armature, and this voltage and the current differ in phase by an angle θ, where $\tan\theta = x_0/r$ and $\cos\theta = r/Z_0$. If a synchronous motor is running and generating a counter e.m.f. e and is connected to bus-bars of voltage E, the current flowing in the armature will be proportional to the vector difference between E and e and inversely proportional to Z_0, all taken per phase.

Vector Relations for Motor Action. — In Fig. 1 let E represent the bus-bar or line voltage (per phase) impressed on the terminals of a synchronous motor. Let e represent the counter e.m.f. of the motor and in this case assume $e < E$ and directly opposed to E. Then the difference between E and e will set up a current in the armature of the motor. IZ_0 will be the voltage and the current will lag behind IZ_0 by an angle θ where $\cos\theta = \frac{r}{Z_0}$. Thus the motor takes a current I lagging behind the impressed voltage E.

Fig. 2 shows the relations when $e > E$, then IZ_0 will be reversed in phase as indicated. I will always lag behind IZ_0 by the angle θ and will be found drawn upward. I lags behind e and IZ_0 but I leads the impressed e.m.f. E by an angle $(180° - \theta)$. Thus when the field excitation is increased so that e tends to

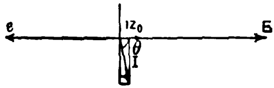

Fig. 1.

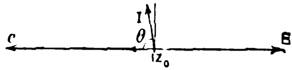

Fig. 2.

become greater than E, the machine takes a current leading with respect to the impressed e.m.f. As in a synchronous generator the field excitation required for a given terminal voltage depends upon the phase relation of the external circuit or the load, so conversely in a synchronous motor the phase relation of the current into the armature at a given terminal voltage depends upon the field excitation and the load.

Fig. 3 shows the relations when e is more than 180 degrees behind E, that is, e is behind the position it had in the preceding examples by an angle α. The vector resultant of E and e will be IZ_0 as shown, leading E. The current I will lag behind IZ_0 by the same angle θ, but is now almost in phase with E and lagging only slightly. Thus power $(EI \cos \phi)$ is being sent into the ma-

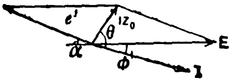

Fig. 3.

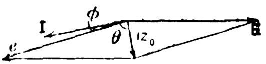

Fig. 4.

chine and it acts as a motor, transforming electrical power into mechanical power. When the machine is running as in Figs. 1 and 2 the power is very small. If, however, a mechanical load is applied, the armature will drop back in position by a slight amount. This causes e to drop back in phase and the machine immediately draws power from the line.

If, as in Fig. 4, power is applied to make the armature move forward and cause e to advance in the opposite direction, the resultant IZ_0 is thrown downward and I, lagging behind IZ_0 by θ, is thrown around almost in phase with e. The machine then becomes a generator, transforming the mechanical power applied into electrical power $eI \cos \phi$.

Synchronous Position. — In the discussion of the action of a synchronous motor it is convenient to employ the term "synchronous position," by which is meant the position which any definite point on the revolving member occupies at the same period of each cycle of time. It is only necessary for the machine to change in synchronous position by a very slight angle α to cause a large energy current to flow. If α should become 90 degrees, theoretically the power would become a maximum, and any increase in α means that θ becomes greater than 45 degrees, the power decreasing and the machine falling out of step. When α becomes 180 degrees a total e.m.f. equal to the sum of e and E is short-circuited by Z_0 and the current is enormous and the power factor low.

Maximum Torque. — If the speed changes for a short instant of time sufficiently to allow a point on the armature to drop back in synchronous position one-half the pitch of one pole (90 electrical degrees), the motor torque will increase from zero to the maximum available in the motor. Thus, for any torque less than the maximum the armature (or revolving field) need only change in speed sufficiently to drop back some distance less than one-half the pitch of a

pole. If the load demands a torque greater than this maximum the armature will drop back more than 90 degrees and will fall out of step and come to rest. In most synchronous motors the maximum torque is about 6 times normal torque.

DESIGN AND CALCULATIONS. — (*See also Generators, Alternating Current.*) The design and calculation of synchronous motors is very much like the design and calculation of alternating-current generators. There is a difference in the proportioning of certain details and there are certain features that are of importance in generators that are not important in motors (i.e., regulation) and the converse is also true.

Armature Reaction. — The armature reaction of a synchronous motor is expressed as $\frac{1.5\sqrt{2}SI}{p}$ for a three-phase machine and $\frac{\sqrt{2}SI}{p}$ for a two-phase machine, where S = turns in series per phase, I = full-load current per phase and p = number of poles. The armature reaction of a motor is usually 30 per cent to 50 per cent greater than that of a generator of the same rating and frequency. The higher value gives greater synchronizing torque per ampere, a better starting torque, and reduces the cross-currents between machines in case of hunting. The armature-reaction ampere turns at full load may be equal to the field ampere turns at no load. Too great an armature reaction is objectionable, because it reduces the energy transfer between two machines and therefore reduces the synchronizing power, that is, the tendency of the machines to hold each other in step.

Excitation. — The excitation of a motor is calculated in the same manner as the excitation of a generator. The magnetic densities are usually a little less. The capacity of the field winding depends upon whether the synchronous motor is to be used as an ordinary motor or to regulate the power factor of a system by over-excitation.

Leakage Reactance. — The leakage reactance may be higher in a motor than in a generator as regulation is not of so great importance. However, too great a reactance will reduce the starting torque of the motor.

Short-circuit Current and Synchronous Impedance. — The short-circuit current of the motor depends upon the leakage reactance and the armature reaction. The short-circuit current and the synchronous impedance may be predetermined from the no-load saturation curve and the calculated leakage reactance per phase.

Let F = excitation in ampere turns per pole for which it is desired to find the short-circuited current,
I = rated current per phase,
x = leakage reactance in ohms per phase,
E = voltage per phase due to F at no load,
S = turns in series per phase,
p = number of poles.

Then the ampere-turns synchronous impedance for full-load current is

$$\frac{2.12\,SI}{p} + \frac{IxF}{E},$$

and the short-circuit current with excitation F is

$$I_0 = \frac{EpF}{2.12\,SE + xpF}.$$

The synchronous impedance at this excitation is $Z_0 = E/I_0$, and the syn-

chronous reactance is $x_0 = \sqrt{Z_0^2 - r^2}$, where r is the resistance of the armature per phase.

Efficiency and Losses. — The losses are predetermined as in a generator. They are: A = friction, B = excitation or field RI^2, C = core-loss, D = armature RI^2; then

$$\text{Efficiency} = \frac{\text{Output}}{\text{Output} + A + B + C + D}.$$

Phase Characteristics or V-Curves. — The phase characteristic is a curve showing the variation in armature current for any given load with varying field excitation. Fig. 5 shows the shape of the curves, which may be determined both by calculation and test. The phase characteristic for any particular load has the general shape of the letter V, and the group of such curves for various loads are frequently called the "V-curves" of the machine. There are two methods of calculating the phase characteristics, the electromotive force method and the magneto-motive force method.

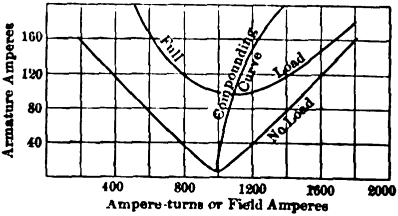

Fig. 5. Phase Characteristics of Synchronous Motor

Electromotive Force Method. —

Let E = line voltage per phase,

e = motor counter e.m.f. per phase corresponding to the excitation to be used,

i = component of current in phase with e,

ei = mechanical output of armature,

i_1 = reactive component of current, positive for leading, negative for lagging,

r = armature resistance per phase,

x_0 = synchronous reactance per phase,

then $E^2 = (e + ri - x_0 i_1)^2 + (x_0 i + r i_1)^2 = e_1^2 + e_2^2$.

E, r and x_0 are constant, e is set by the value of the field current assumed, then i = (watts output)$/e$ and i_1 remains the only unknown quantity. Solving for i_1 the total current $I = \sqrt{i^2 + i_1^2}$ and the power is $e_1 i - e_2 i_1$ (for i_1 lagging). If e is greater than E, then i_1 is leading, and the power factor is $(e_1 i + e_2 i_1)/EI$.

Magneto-motive Force Method. —

Let E = line voltage per phase,

F = field ampere turns per pole for this voltage,

D = any value of field ampere turns per pole,

I = armature current per phase,

i = energy component of current = (power input) ÷ E,

p = number of poles,

ν = field leakage coefficient of machine,

S = turns in series per phase,

i_1 = wattless component of current for excitation D.

Then

$$pF = pD - 2.12\, S i_1 \nu \text{ and}$$

$$i_1 = \frac{pD - pF}{2.12\, S\nu},$$

and

$I = \sqrt{i^2 + i_1^2}$ is the current in armature for power input Ei and for the excitation D assumed. If i_1 is negative ($F > D$) then i_1 is lagging. If $D > F$ then i_1 is positive and leading.

Angular Lag Due to Load (α). — For any load on a synchronous generator there is an angular advance of the generated e.m.f. ahead of the terminal e.m.f., and in a synchronous motor there is an angular lag of the generated e.m.f. behind the terminal e.m.f. This phase displacement is accompanied by a shift in the synchronous position of the armature, which may be calculated and actually measured (*see Tests of Synchronous Motors below*).

To calculate this angle α expressed in electrical degrees (360 degrees per pair of poles), let

E = line or terminal voltage per phase,
e = induced or counter e.m.f. per phase; may be taken from no-load saturation curve for given excitation,
r = resistance of armature per phase,
x_0 = synchronous reactance per phase,
I = current per phase,
ϕ = phase angle between E and I.

Then

$$e^2 = (E - Ir\cos\phi - Ix_0\sin\phi)^2 + (Ir\sin\phi - Ix_0\cos\phi)^2,$$

and

$$\alpha = \sin^{-1}\left[\frac{(Ir\sin\phi - Ix_0\cos\phi)}{e}\right],$$

or roughly

$$\sin\alpha = \frac{I\cos\phi}{\text{short-circuit current}}.$$

The mechanical displacement of the armature for the load $EI\cos\phi$ per phase is $2\,\alpha/p$.

Synchronizing Torque.—The synchronizing power of a machine is a measure of the ability of a machine to keep in step with its supply circuit. It may be expressed in terms of torque per degree of displacement. If P is the kw. output of a motor and α is the angular displacement of the armature in electrical degrees for this load, then

$$\text{Motor torque} = \frac{7050 \times (\text{kw.})}{\text{rev. per min.}},$$

$$\sin\alpha = \frac{(Ir\sin\phi - Ix_0\cos\phi)}{e},$$

and

$$\text{Synchronizing torque} = \frac{7050 \times (\text{kw.})}{\alpha \times (\text{rev. per min.})}.$$

A high resistance between machines reduces the synchronizing torque as it reduces E. A reactance between machines is not as bad as resistance. Increasing the excitation increases e and improves the synchronizing torque.

Hunting; Natural Period. — The rotating part of every synchronous machine acts like a pendulum, tending to swing ahead and behind its normal synchronous position. The mass of the armature (and its flywheel) acts like the mass of the pendulum, and the torque of the machine being proportional to the displacement (α) corresponds to a spring or gravity acting on a pendulum. Such a combination has an "electro-mechanical period" of its own, and if the frequency of this period is in tune with any other pulsating force in the system, such as engine impulses, "hunting" or "surging" may occur.

Boucherot and Kapp have shown that the natural period of any synchronous machine expressed in seconds or fraction of a second is given by the formula:

$$T = 0.308\,N\sqrt{\frac{Wk^2}{fgmEI_0}},$$

where N = r.p.m. of revolving part,
W = total weight of revolving part including any flywheel in pounds,
k = radius of gyration of W in feet,
f = frequency of current, cycles per second,
g = acceleration of gravity, in ft. per sec. per sec. = 32.2,
m = number of phases,
E = terminal voltage per phase,
I_0 = short-circuit current of machine per phase and at excitation used.

The frequency of the natural period expressed in impulses per minute is $f_1 = 60/T$.

The formula shows that the greater the flywheel effect kW^2 (*see Flywheels*) the longer will be the periodic time of a swing. The greater the short-circuit current or excitation the shorter will be the periodic time. The periodic time may be increased by connecting reactance coils in series with the machine between its terminals and the bus-bars.

If T_0 is the periodic time of any other pulsating force in the system, as the strokes of a steam engine, the danger of hunting is greatest when

$$T/T_0 = 1/4,\ 1/3,\ 1/2,\ 1,\ 3,\ 5, \text{ etc.}$$

A tendency to hunt is damped by solid pole pieces, bridges between poles or, best of all, a squirrel-cage winding in the pole face.

Maximum Output. — As the current which would flow during maximum output of a synchronous motor is so great that it would burn up the windings in case this output should last more than a fraction of a second, the value of the maximum output is only of theoretical interest. In practice the maximum output (for a given voltage) is only reached under two conditions: (1) when, due to extraneous causes, the line voltage decreases to a fractional value, the maximum output decreasing as the square of the voltage; (2) when, due to hunting or pulsation, the flow of energy into and out of the machine reaches excessive values momentarily. In one of these swings the power may reach the value of the maximum output or exceed it and the machine shut down. Although the power of the machine drops off gradually after the point of maximum output has been reached, the motor is unstable in this region and is more than likely to shut down when the condition is reached.

Starting Torque. — All synchronous motors must be started either as hysteresis* or induction motors. In the former case the motor requires a high voltage and takes a small current, but as the torque is very slight this method is seldom used in practice. When starting as an induction motor a high armature reaction is desirable and a low leakage reactance. A squirrel-cage winding in the pole face must be provided, and as in an induction motor this squirrel-cage winding must have a cross-section approximating a certain value. If the cross-section is too large, the currents will be excessive and the starting torque not the best. If the cross-section is too small, the currents will be small and the starting torque not the best. While the cross-section of the squirrel-cage winding may be roughly predetermined by treating the ma-

* A piece of iron in a rotating field has a torque produced on it due to the hysteresis and eddy currents set up in it. Such an arrangement may be called a "hysteresis" motor; an open-circuited field of a polyphase synchronous motor therefore forms a hysteresis motor.

chine as an induction motor, this method is not accurate because the construction of the field renders the calculation of the leakage reactance inaccurate. It is thus much better determined empirically.

Rotary Phase Modifiers or Rotary Condensers. — Synchronous motors are sometimes used to improve the power factor and reduce the line current of an installation of a number of induction motors. If a factory has an installation of 100 kw. of induction motors having an average power factor of 71 per cent and taking I amperes, then by installing a synchronous motor of 100 kw. rating, designed to be overexcited, the power available will be doubled and the line current only increased by 41 per cent or to 1.41 I. Such a machine is called a "rotary condenser" and if it is rated at 100 kw. it may give 71 kw. of power and 71 kv-a. to balance the reactive effect of the inductive apparatus. Other relations may be obtained in accordance with the principle of vector combinations.

Let P_1 = true power taken by the induction motors, kw.,
Q_1 = reactive power taken by the induction motors, kv-a.,
$L = \sqrt{P_1^2 + Q_1^2}$ = total kv-a. of induction motors,
P_2 = true power taken by rotary condenser, kw.,
Q_2 = reactive power taken by rotary condenser, kv-a.,
$K = \sqrt{P_2^2 + Q_2^2}$ = total kv-a. of condenser,

then

$$\text{Line kv-a.} = \sqrt{(P_1 + P_2)^2 + (Q_2 - Q_1)^2}.$$

TESTS OF SYNCHRONOUS MOTORS. — Certain tests on synchronous motors are the same as those made on an a-c. generator; the methods of carrying out such tests are described in the article on *Generators, Alternating Current*. The first five of the following tests are of this character:

1. Resistance of armature and field circuits both cold and hot.
2. Saturation curve at no load and under special circumstances at full load.
3. Core-loss.
4. Short-circuit or synchronous impedance.
5. Insulation tests.

6. **Phase Characteristics or V-Curves** at no load, full load and any other specified load. The machine is operated as a motor with the specified load kept constant throughout the run. The voltage and frequency impressed upon the motor are also kept constant. The current in the field is varied from the minimum at which the motor will operate to the maximum (from ¼ normal to 1½ normal) and the variation in current input to armature noted. Readings are taken of load, volts armature, amperes armature and amperes field. A curve is plotted with amperes armature as ordinates, and amperes or ampere turns per pole in field as abscissae. This gives the characteristic V-curves of the synchronous motor (see Fig. 5). The point of minimum current input for each load is very clearly shown. At this point the power factor is unity. At lesser values of field current the armature current is lagging and the power factor poorer. At greater values of field current the armature current is leading. The point of minimum current occurs at a higher value of field current for the greater loads because the field excitation must be increased with the load to overcome the armature reaction due to the load current.

Compounding Curve. — The curve connecting the points of minimum armature current in the group of V-curves is called the compounding curve for unity power factor.

7. Starting Tests. — A low voltage is impressed on the armature and gradually increased until the motor starts. The field circuit is open in two or more places and a high potential voltmeter connected across one section to determine the voltage induced in the field spools by the rotating magnetic flux. The test is repeated for several different initial positions of the revolving part and a record is made of the time required for the machine to reach synchronism. The time at which synchronous speed is reached may be determined by the fact that the induced voltage in the field becomes zero. Readings are taken of volts armature, amperes armature, initial position, maximum volts field, time to reach synchronism. See also section on *Starting*, below.

8. Armature Phase Position. — The phase position of the armature discussed previously may be measured, although the item is only of theoretical interest and not of commercial importance. A synchronous motor is supplied with power from a special alternating-current generator, and on the end of the shaft of each machine is placed a contact-making disk, as shown in Fig. 6.

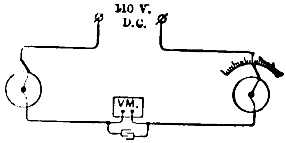

Fig. 6. Contact Method of Measuring Armature Phase Position

A voltmeter is connected in series with a source of direct current, the two disks, and the brushes pressing on the disks. The voltmeter reading is a maximum when the two brushes are in contact with the metal strips at the same time. The brush on the motor may be moved over a graduated scale or arc, so that its position may be varied and the actual angular movement measured. The brush on the generator remains stationary. As the load on the motor is increased it will be found necessary to move its brush in order to keep the voltmeter reading at its maximum value, and the angle β through which the brush has been moved for the change in load gives the phase position of the motor armature with respect to the generator armature. It will be found that the value of β is directly proportional to the load. The difference in phase of the electromotive forces in electrical degrees will be β multiplied by the number of pairs of poles of the motor. If hunting exists, the maximum angle of swing may be determined by moving the motor brush first one way as far as the effect may be noticed, and then in the other direction. (*See Morecroft, Laboratory Manual.*)

SPECIFICATIONS. — Synchronous motors are rated in the same manner as synchronous generators, and the same heating limits and specifications apply. (*See Generators, Alternating Current.*) It is customary to specify the value of the current taken by the motor in starting with no load other than the friction of its own bearings, or its own friction plus that of the machine to which it is connected, in case it is part of a motor-generator set. It is also sometimes mentioned in the specifications that the motor will not hunt providing the total resistance drop between the generator and motor is less than some specified value (10 per cent or 15 per cent).

INSTALLATION AND OPERATION. — The precautions to be taken in installation are the same as for a-c. generators (q.v.). Direct current must be provided for excitation. If a synchronous motor is operated on a polyphase system having unbalanced voltages it will take unequal currents in the different lines and tend to balance the voltages. These unequal currents, however, increase the heating somewhat for a given load.

Starting. — Provision must be made for a reduced voltage for starting the motor, either by means of taps on the transformers or by means of a starting compensator (q.v.). Large motors require two steps in starting, ⅓ and ⅔

of normal voltage. Small motors will start with one step at ½ voltage. The field circuit is opened by the field "break up" switch and a voltage applied to the armature. When the armature current has decreased from its large value at starting to a reasonable value the voltage is increased, step by step. When the motor has reached maximum speed the field is excited and the motor pulls into exact synchronism. The field current is then adjusted until the condition of minimum armature current is found or until the power-factor indicator records unity power factor. The load may then be applied.

If a synchronous motor is to be started often (several times a day) it is desirable to provide a special starting motor which brings the synchronous motor up to a speed a little above synchronism. Synchronizing must then be effected as in a-c. generators. Such a motor would require only about 30 per cent of the full-load current of the motor, and therefore have very little effect on the regulation of the system and not cause disturbance to the lights and other motors on the system. It usually requires less than a minute to bring a motor up to speed.

DIMENSIONS, WEIGHT AND COSTS. — These are approximately the same as for synchronous generators of the same kv-a. rating. (*See Generators, Alternating-Current.*)

[W. I. Slichter.]

OHMMETERS. — (*See also Bridges for Electrical Measurements; Galvanometers.*) The name ohmmeter is applied to any portable device designed for the direct measurement of electrical resistance. The simplest form of ohmmeter consists of a slide-wire bridge, battery and galvanometer all mounted in a portable case. Another form of ohmmeter utilizes a special form of galvanometer whose deflection, measured on a properly calibrated scale, gives the value of the unknown resistance directly in ohms.

BRIDGE TYPE OF OHMMETER (Fig. 1). — This ohmmeter is based on the Wheatstone-bridge principle, but differs from most Wheatstone bridges in that the rheostat resistance R is kept constant and bridge arms, formed by the wire W, are varied by moving a contact C. Ohmmeters of this type are made in many varied forms. In some a straight slide wire is stretched over a cardboard scale and contact on the wire made with a metallic stylus. In others a slide wire is wound on an insulating cylinder.

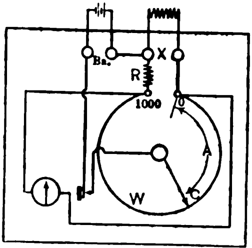

Fig. 1. Slide Wire Ohmmeter

A satisfactory type is that in which the slide wire is mounted on a disk and the disk rotated, the contact being fixed. A high-resistance slide wire is secured by winding a helix of insulated wire on a small mandril and mounting it on the periphery of the disk, removing the insulation from the wire where the contact touches.

The scale may be equally divided into a thousand parts, or may be divided to read directly the ratio of the resistance measured to the resistance of the fixed rheostat resistance R.

When provided with a direct-reading scale, the slide-wire ohmmeter is an exceedingly useful instrument for factory work, where a large number of resistances of various magnitudes are to be measured, and no great accuracy of measurement is required. Where a great number of resistances all having approximately the same value are to be measured, the instrument can be made with a scale covering a small range and good accuracy secured.

It makes a convenient instrument for cable-testing work, especially when provided with telephone and buzzer, as the set may then be used to locate opens by a capacity method. When so equipped it is also possible to measure resistances where earth currents would make ordinary Wheatstone-bridge measurements impossible, as in measuring the ground resistance of lightning rods, etc.

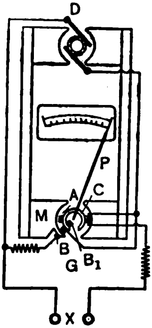

Fig. 2. Evershed Megger

EVERSHED MEGGER (Fig. 2). — This instrument is of the galvanometer type. It is principally useful for the measurement of insulation resistances and other high resistances where extremely high accuracy is not required. The scale is graduated to read directly in megohms, whence the name.

Referring to Fig. 2, D is a small d-c. generator and G a special form of pivoted galvanometer, consisting of a permanent magnet M, a soft iron core C, a current coil A and two pressure coils B and B_1. These three coils are rigidly attached at a fixed angular distance apart to the shaft which carries the pointer P. The generator and galvanometer are mounted in a single box provided with two binding posts for

connecting the unknown resistance X and a handle for turning the armature of the generator by hand.

The coil BB_1, called the pressure coil, is permanently connected across the terminals of D. The current coil A is made to move through an annular gap in such a manner that the field in which it moves is uniform, whereas the pressure coils BB_1 move from a position midway between the poles, where the field is at a minimum, into a stronger and stronger field, the connections being such that the torque due to the current in the current coil is opposed by the torque due to the current in the pressure coil. With no current in the current coil, that is to say, when the resistance to be measured is infinite, current through the pressure coils will cause them to come to rest with their plane at right angles to the magnetic field. When the current through the current coil is increased by putting in lower resistances the current coil drags the moving system round in a clockwise direction; since the pressure coils come into a stronger and stronger field, the resistance to this motion becomes greater and greater. Hence a definite position is assumed by the system for the particular resistance at X.

An increase in voltage would increase the current in both current and pressure coils in the same proportion; consequently the instrument is independent of the voltage of the generator.

To test the insulation of a circuit it is only necessary to set the megger down on a fairly level base, connect the circuit wires to the line and earth terminals, and give the generator handle half a dozen rapid turns, when the index promptly comes to rest and points to the resistance in megohms.

In the cheaper instruments the generator gives a variable voltage depending upon the speed of rotation of the handle. In the higher priced instruments the generator is designed to give a constant voltage for a considerable range in the speed of driving. The voltage at which an insulation test is made is often of great importance (*see Resistance and Conductance*).

COST, RANGE AND ACCURACY. — Bridge type ohmmeters range in price from $35 for ohmmeters having a range of from 0 to 100 ohms and an accuracy of about 2 per cent to $80 for ohmmeters having a range of from 0 to 10,000 ohms and an accuracy of about ½ per cent. Meggers range in price from $187.50 for variable-voltage meggers having a range of from 0 to 10 megohms and an accuracy of about 5 per cent to $375 for constant-pressure meggers having a range of from 10 to 2000 megohms and an accuracy of about 4 per cent.

[H. Pender and H. R. Ranken.]

OIL, TRANSFORMER. — (*See also Transformers; Circuit Breakers; Insulating Materials, Testing of.*) While mineral, vegetable and animal oils when pure are all good insulators, mineral oils obtained from petroleum products are almost universally adopted for use in transformers and switches. The mineral oil employed for this purpose is commonly called Transil Oil.

Mr. D. B. Rushmore gives the following as the characteristics of oil usually furnished with large, high voltage, water-cooled transformers:

Flash point	130° C.
Burning point	145° C.
Freezing point	−15° C.
Color	white
Spec. gravity at 15.5° C.	0.830
Viscosity (Saybolt 40° C.)	40

Dielectric Strength and Specific Inductive Capacity. — Fig. 1, from Hendrick's paper, gives the puncturing voltage of dry transformer oil for variously-shaped electrodes. These are standard curves suitable for use in design. They are based on the same data as those given by H. W. Tobey (*see Bibliography*). The tests were made under the following conditions:

Curves. — For 4-in. disks; 2-in. balls; 1-in. blunt conical points; needle points; 4-in. disk and needle point. *Material.* — Heavy transformer oil. *Dimensions.* — Specific gravity, 0.868; viscosity at 40° C. = 100 Saybolt. *Composition.* — From Pennsylvania crude. *Treatment.* — Filtered through dried blotting paper. *Method of test.* — Beginning at lowest voltage, each curve is taken up to highest voltage and down again — about 10 to 15 points being taken on each curve. Standard test on oil at beginning and end shows that quality remained nearly constant. *Temperature.* — 20 to 25° C. *Time.* — Instantaneous. *Frequency.* — 60. *Wave.* — Sine. *Number of trials.* — Each point, about five. *Accuracy of curves.* — Plus or minus 10 per cent. *Characteristics.* — (Fig. 1.) Puncture voltage depends very largely on shape of electrodes. Curve 1 — using 4-in. disks. Curve 2 — using 2-in. balls. Curve 3 — using 1-in. blunt conical points. Curve — 4 using needles. Curve 5 — using 4-in. disk and needle.

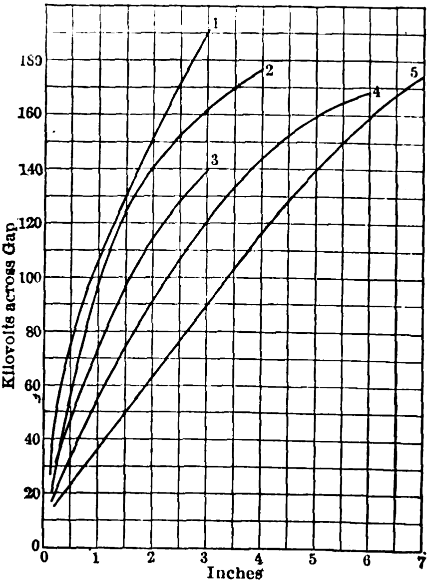

Fig. 1. Puncturing Voltage for Dry Transformer Oil

The specific inductive capacity as determined from these tests was 2.5 between 25 and 100° C.

Effect of Moisture on Dielectric Strength. — The effect of moisture in oil is shown in Fig. 2, which curve is taken from Hendrick's paper (*see Bibliog-*

raphy). The conditions were as follows: *Material.* — Heavy transformer oil. *Dimensions.* — Specific gravity, 0.87; viscosity at 40° C. = 100 Saybolt. *Composition.*—From Pennsylvania crude. *Treatment.* — Oil is first filtered through dry blotting paper, and oil and water then emulsified by mechanical shaker. *Method of test.* — Standard spark gap 0.2 in. between 0.5-in. disks; two separate emulsions; four samples of each; five trials on each sample. *Temperature.* — 20 to 25° C. *Time.* — Instantaneous. *Frequency.* — 75. *Wave.* — Sine. *No. of trials.* — Each point, 40. *Accuracy of curve.* —Plus or minus 5 per cent. *Characteristics.* — Extremely rapid reduction of dielectric strength by minute quantities of water—under 0.01 per cent if thoroughly mixed. *Specific capacity.* — Dry oil = 2.5 at 25 to 100° C. *Notes.* — Practically identical results obtained on light oil whose specific gravity was 0.85 and viscosity at 40° C. was 40 Saybolt.

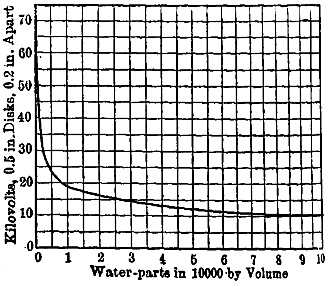

Fig. 2. Effect of Moisture on Puncturing Voltage

Methods of Removing Moisture; Chemical Treatment. — Drying agents, such as calcium chloride, calcium oxide (unslaked lime), calcium carbide and metallic sodium, respectively, are mixed with the oil in the proportion of 6 parts of dehydrating material to 100 parts of oil by weight. To be effective the mixture must stand for three or four days before the drying agent is filtered off. Calcium chloride works faster and more efficiently than any of the other materials mentioned and is most commonly used.

Heat Treatment. — Oil heated to a temperature of 105° C. is rendered quite dry but there is great danger of injuring the oil by overheating. If the pressure on the oil is reduced when heated, the moisture may be evaporated at a lower temperature, thereby reducing the danger of overheating. Dry air blown through moist oil will take up much of the moisture, especially if used in connection with either of the above heat treatments.

Separation by Gravity. — When the oil contains a large amount of water, the water will settle to the bottom if the oil is left undisturbed for a number of days. The dry oil may then be drawn off from the top.

Centrifugal Separation. — If moist oil is placed in a centrifugal separator similar to the De Laval cream separator, most of the water will be forced into the outer casing and the remainder may be extracted by passing the oil through a filter.

Paper-filter Treatment. — When moist oil is forced through a paper filter, the water content will not pass through the filter. Since the process is slow in a gravity filter, high-pressure filters are used in which a pressure pump forces the moist oil through several layers of blotting paper. This type of filter press is especially convenient since the moist oil may be drawn from the bottom of a transformer case, dried in a filter press and fed into the transformer case again at the top. In this method, the oil is not only dried but is also freed from dirt and other foreign matter. (*Bibliography reference, H. W. Tobey.*)

Effect of Temperature on Puncturing Voltage and Insulation Resistance. — The curves in Fig. 3, taken from Tobey's paper, show the effect

of temperature upon the dielectric strength and insulation resistance of transformer oil. Tobey also found that at about −8° C. the dielectric strength increases very rapidly with further decrease of temperature.

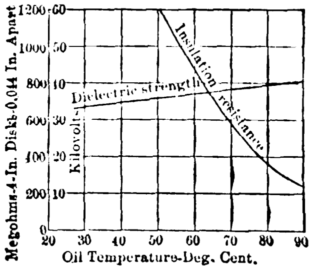

Fig. 3. Effect of Temperature on Puncturing Voltage and Insulation Resistance of Transformer Oil.

TESTING OF TRANSFORMER OIL. — The puncturing voltage, insulation resistance and specific inductive capacity of oil is determined in much the same manner as for other dielectrics; see *Insulating Materials, Testing of.* Full directions for making all the necessary tests on oil are given in a paper by C. E. Skinner, *Elec. Club Jour., Vol. 1, p. 227.*

Test for Moisture. — The presence of moisture in oil can be detected by the hissing sound produced when a very hot nail is dropped into it. A bluish tinge given anhydrous copper sulphate placed in oil also indicates the presence of moisture.

Flash and Fire Tests. — In the "open test" for the flash point of an oil, about 50 cc. of the dry oil are heated in an open vessel. The oil should be heated slowly and uniformly and the temperature noted by a thermometer immersed in the oil. From time to time a small flame is brought on to the surface of the oil and the lowest temperature at which a slight explosion or flash takes place is called the "flash point." In the "closed test" the oil is placed in a closed vessel, the cover of which is perforated with several holes, which may be opened or closed. The oil is heated as in the "open test" and is stirred by a shaft which passes through the center of the cover. To determine the flash point, the holes in the cover are opened simultaneously and a small flame is then directed upon the surface of the oil through one of the openings. The fire test, in which the ignition point of the oil is determined, is carried out in a similar manner as that for the flash point. The ignition point is the lowest temperature at which the oil will continue to burn after a flame has been brought in contact with its surface for a few seconds. (*J. Lewkowitsch, see Bibliography.*)

Evaporation Test. — A small quantity of the oil is dropped upon a watch glass, and, after being carefully weighed, is placed in a constant-temperature oven for a number of hours. The temperature and duration of the test should conform as far as possible with the conditions under which the oil is to be used. After heating as indicated, the oil on the watch glass should again be weighed carefully to note the shrinkage. In general, a test at 50° C. for a period of 24 hours should not show an evaporation of more than 1 per cent. (*Bibliography reference, A. H. Gill.*)

[R. G. HUDSON.]

OSCILLOGRAPHS. — (*See also Braun Tube; Wave Analysis.*) The oscillograph is essentially a galvanometer of very short period. It is applied in the observation of potentials or currents, as voltmeter or ammeter, mainly when variations are too rapid to be indicated by the more usual instruments; for example in observation of potential waves of generators, potential and current waves in inductive apparatus, short-circuits or switching of transmission lines. As in many cases it is necessary to have two or more curves taken together in their relative phase relation, more than one element is necessary in a practical instrument; it is regularly built as a three-element oscillograph, giving one, two or three curves, as may be required, on the record. One element may be used as a chronograph by connecting it to record a timing wave from an a-c. source of known frequency.

Types of Oscillographs. — The most common form of oscillograph is the moving-coil type, the "coil" being two small thin strips or ribbons arranged very close together, thus forming the two sides of a coil of one turn. A moving iron vane can also be used, but this type has not received extended practical application. The electrostatic oscillograph, which is particularly well adapted for direct observation of high potentials, consists of two insulated strips maintained at a constant potential difference, these strips being caused to vibrate by the varying force of attraction and repulsion due to the charges on two fixed plates connected to the varying high-potential source. The vibrator is similar in construction to the vibrator of the ordinary oscillograph, except that the two strips are connected by a light insulating thread. The strips are connected to the terminals of a storage battery, the middle of which is kept at a potential midway between the potential of the two plates, by being connected between two equal condensers in series across the attracting plates. Still another form of oscillograph is the cathode ray, or Braun, tube; see article on *Braun Tube*. This last type of oscillograph finds its most valuable application in the laboratory study of high-frequency and high-voltage phenomena which are beyond the range of the ordinary oscillograph. The practical application of this type has been found rather difficult.

DESIGN OF MOVING-COIL OSCILLOGRAPH. — The ordinary or moving-coil oscillograph is described in detail below.

Construction of Vibrator. — The vibrator, or moving element (Fig. 1), consists of two strips of flattened wire stretched over bridges, with a very small mirror cemented directly to the strips; the arrangement constitutes a one-turn galvanometer coil of elementary form. The vibrator is placed between the wedge-shaped poles of an electromagnet or of a permanent magnet. It is immersed in a liquid which provides critical damping. The vibrator conductor passes from one terminal post T over the bridges BB_1 in narrow grooves, over a pulley P, back over the bridges in grooves very close to the former, to the other terminal post T_1. The width of the strip is usually 0.005 inch to 0.007 inch. The mirror M is cemented to the strips midway between the bridges, its usual size being 0.060 inch by 0.017 inch. Tension is applied to the strips, for the ordinary vibrator 6 oz. for the two strips, indicated by a small spring balance SB. The vibrator is readily rewired in case of break or burn-out.

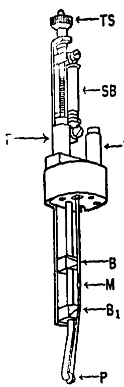

Fig. 1. Oscillograph Vibrator. B,B1 bridges for supporting strip; P, pulley; SB, spring balance indicating tension; TS, tension screw; M, mirror

For efficient operation vibrators are made interchangeable. This is necessary to make expeditious operation possible, and to minimize delay due to accidental destruction of vibrator parts.

Construction of Field Magnets. — The galvanometer field is an electromagnet with wedge-shaped poles. The vibrator is so mounted that the strips lie in the narrow air gap between these poles. A direct current through the winding of the electromagnet produces a very strong field in this air gap. The ampere turns of the electromagnet are sufficient to saturate the pole tips and render the strength of the field practically independent of the voltage applied to the electromagnet windings, at least for ordinary voltage variations. One terminal of the vibrator may be connected electrically to the core of its field magnet, each core being insulated from its field winding for a working pressure of 2,300 volts.

A permanent magnet can be substituted for the electromagnet as the oscillograph field. This construction is practicable for two elements. The permanent magnet oscillograph is somewhat inferior in sensibility, and greatly inferior in insulation between elements, compared with the electromagnetic type of oscillograph.

Optical System. — The light for the oscillograph from a projection arc lamp enters the case at the shutter aperture, and, after being reflected toward the vibrator cell by a total reflecting prism (one for each element), passes through a slit which adjusts the width of the image. It is then reflected by the small vibrator mirror, and passes through a cylindrical lens to the image on screen or film. Very careful adjustment of the optical system is essential to secure records of good photographic intensity.

The arc lamp used as a source of light for the oscillograph is usually a hand-feed lamp with small carbons at right angles, taking 5 to 8 amperes, with *solid positive* carbon in the horizontal position. The light is rendered parallel by a simple projection lens. Any convenient arc lamp, however, may be used with good results. If only an a-c. source is available for the arc, records of fluctuating intensity are obtained, which, however, are usually legible throughout their length. Sunlight source with a heliostat, when circumstances permit, gives photographic records of superior intensity.

The astigmatic optical system of the oscillograph, due to the cylindrical lens, is quite a distinctive one; the geometrical light source for the image in the vertical direction is the adjustable slit, in the horizontal direction it is the vibrator mirror.

Means for Obtaining Photographic and Visual Records. — The photographic record is taken on a moving film or plate. The most practical arrangement is a film, having a length of about 12 inches, on a drum driven at suitable speed by a small motor. A contactor opens the shutter for one revolution of the drum, giving exposure once over the film. The exposure can be adjusted to start at the beginning of the film, or if a record is taken in response to a signal, as of switching or short-circuit, the exposure can be started instantaneously at any part of the film. A long film is desirable in some cases, as in transmission line switching, where the whole disturbance lasting perhaps several seconds is to be taken. By the use of a suitable attachment for long films, records can be taken on films 3 to 5 feet in length.

The motion of the spot of light reflected from the vibrator mirror may be projected as a standing wave on a tracing table, for examination or demonstration. An oscillating mirror, actuated by a cam driven by a small synchronous motor, is given a uniform angular velocity during alternate cycles of the current or voltage observed, and draws out the wave longitudinally. Only alternate waves or cycles are utilized, the intervening waves being cut off by a revolving screen on the motor shaft during the return motion of the mirror. The recur-

rences of the waves are so rapid as to produce an image sensibly continuous to the eye. The synchronous mirror is removed by shift of a simple mechanism to permit photographic record to be taken in the usual manner by revolving film.

Free Period of Vibrator. — The free period of the vibrator is about 1/6,000 second, but some have been constructed to have a free period as high as 1/10,000 second. The higher the free period the less the distortion of the higher harmonics in the current and voltage waves. A free period of 1/6,000 second, is ample to secure practically accurate values of all harmonics having a frequency of less than 1200 cycles per second; with a free period of 1/10,000 second harmonics having a frequency as high as 2000 cycles per second are recorded with practical accuracy.

The free period of a vibrator depends upon the moment of inertia of the vibrating system and upon the tension on the strips; the less the moment of inertia and the greater the tension, the shorter will be the free period. The free period of a given vibrator may therefore be slightly shortened by increasing the tension on the strips, but this in turn decreases the sensibility, i.e., the deflection for unit current through the strips.

To measure the free period of a vibrator it is placed in the cell between the poles of magnet, in the usual way, but with no damping liquid in the cell. It is connected to a d-c. source through an interrupter which makes or breaks the circuit one or more times during the exposure of a film running at as high a speed as possible. The free vibration in decreasing amplitudes is shown on the film, and the period is readily counted, the film speed being known.

Sensibility of Oscillograph. — An oscillograph having a free period of 1/6,000 second requires from 0.1 to 0.2 ampere through the vibrator to give a curve of good amplitude; or about 0.006 ampere is required to give a millimeter deflection from the zero line on the film or tracing table. As ordinarily constructed a deflection of 45 mm. on each side of the zero may be obtained, but a deflection of more than 30 mm. is seldom necessary. The resistance of the vibrator is from 1 to 1.5 ohms; hence to obtain a deflection of 30 mm. about 0.2 volt is required across the vibrator terminals. The sensibility of a vibrator may be much increased by using thinner strips and smaller mirrors, but such arrangements are more delicate and should be used only to meet special requirements.

CONNECTIONS AND ADJUSTMENTS. — For potential, or voltage, curves the oscillograph is connected similarly to a voltmeter; E in Fig. 2. A suitable amplitude of curve is obtained by an external adjustable resistance.

For current curves the oscillograph is connected similarly to a millivoltmeter across a non-inductive shunt; I in Fig. 2. A shunt potential drop of at least 0.1 volt is required, but for convenient adjustment it should be larger, 0.5 volt being a suitable value where practicable. If the current measured is less than 0.2 ampere, no shunt is used, the whole current being taken by the vibrator.

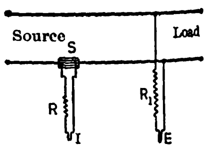

Fig. 2

For waves of flux distribution in generators or motors, the oscillograph is connected to give the voltage of an exploring coil; sometimes in d-c. machines the voltage between commutator bars can be used.

Potential and current transformers are used where the line voltages and currents are too high for practical or convenient direct observation. The oscillograph potential circuit can be connected to the potential transformer along with voltmeter or other instruments, as it is only a fraction of the rated

potential transformer load. For current curves a shunt is connected in the current transformer secondary circuit.

Adjustment of Vibrator and Optical System. — Individual vibrators are provided with movements for vertical and horizontal adjustment of the image. The beam of light is brought vertically to the middle, or axis, of the cylindrical lens; this adjustment is left unchanged, but should be examined occasionally to insure its correctness; this may conveniently be done by viewing the position of the light spot on a thin sheet of paper held against the case where the light comes through to form the image on film or ground-glass screen; the light spot should appear central in the aperture. The horizontal adjustment brings the image to the proper position on the record, and is changed freely according to circumstances. When two curves are to be taken on the record, the images are usually placed for clearness so as not to overlap. If, however, the phase relation is important they are placed with their zero positions near together; it is better not to make them coincident, however, as good superposition is not always secured. After the principal exposure, an auxiliary exposure for zero line is taken with vibrator circuit opened, except in occasional records where the zero line is unnecessary.

Quantitative Measurements with Oscillograph. — The values of the curves may be obtained quantitatively when necessary by reference to a d-c. measurement. For potential curves an observation is taken of a d-c. source of known voltage; for current curves similarly an observation is taken of a measured d-c. current. During these d-c. measurements the resistances in the vibrator circuit should be the same as used during the observations. If a number of observations are taken at different resistances, two or three d-c. calibrations can be made with known resistances, and the calibration for the other resistances computed, assuming the deflection proportional to the total resistance of the vibrator circuit. When potential and current transformers are used, the voltages and currents as directly measured are reduced to terms of line voltages and currents by the transformer ratios. In case of short-circuit currents, where it is not practicable to obtain d-c. currents comparable in amount with those of the observation, a measured d-c. voltage, as from dry cells, can be applied to the oscillograph leads detached from the shunts, the corresponding currents being computed from the shunt resistances.

In many cases, the curve is self-calibrating, a portion of the curve being at a constant d-c. value which can be measured by d-c. instruments, as for instance on generator-field voltage and current curves of short-circuits.

COST OF OSCILLOGRAPH. — An oscillograph complete with a three-element electromagnet galvanometer, optical system, shutter and shutter-operating mechanism, motor and countershaft, photographic and tracing attachments, six film-holders, and the following repair parts: 6 extra suspension strips; 6 vibrator mirrors, 1 box special gold-leaf fuses, 1 bottle mirror cement, 1 bottle damping liquid, costs about $650.

BIBLIOGRAPHY.— Some of the more recent articles on oscillographs are the following: Robinson, L. T., *The Oscillograph and its Uses*, Trans. A.I.E.E., 1905, Vol. 24, p. 213; Ramsay, D. [L. T. Robinson.]

PAPER, IMPREGNATED. — (*See also Insulating Materials; Wires and Cables, Insulated.*) Wires and cables may be insulated by winding paper ribbon helically around the conductor in successive layers until the desired thickness of insulation is obtained. The paper-covered cable, after being thoroughly dried in a hot vacuum dryer is immersed in resin oil until saturated, and then passed through a lead press, which covers it with a continuous sheathing of lead. The paper serves the double function of affording a conveyance for the oil and a mechanical separator between the conductor and sheath. The oil forms the main insulation.

THE PAPER. — The most commonly used paper for such cables is that made of Manila hemp or musa textilis, a fiber grown in the Philippine Islands for rope making. The original fibers are about 6 millimeters long and have a diameter of 0.024 millimeter but the length is materially decreased in the process of beating described below. The paper made from this fiber is not necessarily the best for cable insulation, but the fact that it has stood the test of twenty years use makes American manufacturers slow to try others. Hemp papers are often called Manilas, and at the present time mixtures of hemp and musa have come into general use, a common proportion being one of hemp and two of musa. Jute is sometimes added, but as it is not permanent and adds nothing to the strength, it should be avoided. German manufacturers are using papers containing long fiber wood-pulp in large quantities, or even made exclusively of such wood-pulp, and claim that they are better than Manila papers (*C. Beaver*).

Manufacture of the Paper. — The process of manufacturing Manila paper is as follows. The fibers are cut up, placed in a boiler with lime or caustic soda and boiled under a pressure of from 30 to 50 pounds for between 5 and 10 hours. They are then emptied out, washed free of alkali and put in a breaker where the fibers are partially disintegrated and washed. Sometimes bleaching is performed at this stage, by adding chloride of lime and again washing. The material is then put into the beater, where it is reduced to the condition necessary for the paper machine. After suitably diluting the material it is passed over sand tables, where gritty matter is deposited and then through strainers, where any coarse particles are retained. It then passes in a continuous flow to the endless wire of the Fourdrinier machine, where the fibers are deposited in the form of a sheet; then to the couch rolls and to the press rolls, where the water is squeezed out. Finally it passes over a series of drying cylinders where it emerges dry and is taken upon reels. (This description is abstracted from a paper by C. Beadle and H. P. Stevens; see *Bibliography*, below.)

Necessary Properties of the Paper. — The paper should have the following qualities.

1. Porosity, in order that it may hold a large amount of oil.
2. Strength and elasticity, in order that it may not break either while being wound or while suffering shrinkage in the dessicator.
3. Freedom from mineral matter, not only to give greater porosity but to avoid electrical weakness.
4. Freedom from alkalies, in order that the impregnating oils shall not be saponified.
5. Freedom from metallic salts, such as chlorides and sulphates, in order to avoid short-circuiting the oil by an electrolyte and also to avoid injuring the conductor.

Strength of the Paper. — The strength of paper is usually stated in terms of the length of a piece the weight of which would be equivalent to its breaking strength. Thus a high-class Manila paper gave the results in the accom-

panying table, the humidity of the air being 65 per cent and the temperature 17° C. (Beadle and Stevens.)

Strength	Elongation
	Per cent
11,450 meters, lengthwise. .	2.8
4,450 meters, crosswise. . . .	7.8
7,950 meters, average.	5.3

The average ratio of longitudinal to transverse strength as determined by C. Beaver from tests on several hundred tons of satisfactory insulating paper is about 2.02. The average elongations were 2.2 per cent for the longitudinal direction and 4.4 per cent for the transverse direction.

OIL FOR IMPREGNATING. — Considerable mystery is maintained by the manufacturers respecting the exact nature of the oils used for impregnating the paper, but the principal ingredient is resin oil, the fluidity of which is reduced to a suitable degree by the addition of resin. One manufacturer brings the resin into chemical combination with the oil.

SPECIFIC RESISTANCE OF IMPREGNATED PAPER. — The specific resistance of impregnated paper for wire and cable insulation depends upon the dryness of the oil and upon the nature and quantity of the substances mixed with it. Increasing the fluidity within certain limits reduces the resistance, increases the flexibility and improves the dielectric strength. The value of K in the formula $M = K \log \frac{D}{d}$ (*see article on Rubber*) varies from less than 1000 to more than 3000, the usual value being near the lower limit.

Temperature Coefficient of Resistance. — The effect of temperature changes upon the resistance of oiled paper is greater than upon rubber and less than upon varnished cloth. The accompanying table is representative of a typical paper insulation, but the properties of different makes vary considerably.

Temperature, °F.	Per cent of resistance at 60°
60	100
65	62.5
70	42.6
75	30
80	23.3
85	18.5
90	15.2

DIELECTRIC STRENGTH. — The dielectric strength of oiled-paper insulation is a very indefinite quantity. It is greatly reduced by the presence of even the minutest trace of moisture and it decreases rapidly with increasing temperature. The gradual ionization of vapor is another cause of decreased dielectric strength. It is therefore not surprising to find different experimenters reporting widely different values of this quantity. Thus, E. Jona says that the average commercial impregnated paper subjected to dielectric stress for an hour with progressively increasing potential, will stand from 8 to 10 kilovolts (effective a-c.) per millimeter and that it is not uncommon to find samples with 20 or 30 per cent greater dielectric strength. E. J. Berg gives 250 to 300 kilovolts per inch, or 10 to 12 kilovolts per millimeter. P. Humann says that high-grade impregnated paper will stand 20 kilovolts per millimeter. The usual testing strength H, in the formula

$$V = \frac{H}{r \log_\epsilon \frac{D}{r}}$$

is about 4 kilovolts per millimeter or 100 kilovolts per inch, but the validity of this formula when applied to compound oils is very doubtful on account

of the heterogeneous nature of the insulation. When impregnated paper is punctured electrically, the paper itself chars, so that even though the oil tends to flow into and repair the gap the short-circuit is maintained (*see Wires and Cables, Insulated*).

SPECIFIC INDUCTIVE CAPACITY. — The specific inductive capacity of plain Manila paper (without oil) is 1.8 (*H. Floy*), while that of Manila paper impregnated with a mixture of resin oil and resin is between 2.4 and 2.6. During operation the constituents of the oil which have higher specific inductive capacities are drawn toward the conductor and tend to remain there permanently, thereby affording a natural grading for the cable.

SPECIFICATIONS. — Specifications for impregnated paper insulation for wires and cables will be found in the article on *Wires and Cables, Insulated.*

[W. A. DEL MAR]

PERMUTATIONS AND COMBINATIONS. — (*See also Factorials.*) Each of the *arrangements* which can be made by taking some or all of a number of things is called a permutation.

Each of the *groups* or *selections* which can be made by taking some or all of a number of things is called a combination.

The number of permutations of n things taken r at a time is

$$n(n-1)(n-2)\ \ldots\ (n-r+1).$$

The number of combinations of n things taken r at a time is

$$\frac{n(n-1)(n-2)\ \ldots\ (n-r+1)}{r(r-1)(r-2)\ \ldots\ 3.2.1}.$$

The number of combinations of n things taken r at a time is equal to the number of combinations of n things taken $(n-r)$ at a time.

[W. A. DEL MAR]

PHOTOMETRIC QUANTITIES. — (*See also Illumination, Laws of; Photometry; Vision, Laws of.*) The names and sense of the common photometric units are conventional, though a uniform value of the basic unit of the system, viz., the international candle, was established in 1909 by the national standards laboratories of Great Britain, France and the United States. The standard unit in Germany is the Hefner unit, but the relation that 1 Hefner unit equals 0.9 international candle was officially recognized. The terminology and definitions that follow are in agreement with those recognized by the Geneva Congress in 1896 and the proposals made by the Committee on Nomenclature and Standards of the Illuminating Engineering Society in 1912 (*Trans. Ill. Eng. Soc., Vol. 7, p. 723. See also Standardization Rules of the A.I.E.E.*)

LIGHT FLUX is a measure of the rate of flow of light from a luminous body. It is not identical with the flow of radiant energy but is an evaluation of radiation in terms of the corresponding light sensation. Light flux is proportional to two factors, power radiated and a stimulus coefficient $K\lambda$. The stimulus coefficient varies with the wave-length of radiation as shown in Fig. 1 in the article on *Vision, Laws of*. (*See also Phil. Mag., Vol. 24, p. 853.*)

Lumen. — The lumen, or unit of light flux, denotes the light radiating within one steradian from a source having a uniform luminous intensity of one candle. The steradian, or unit solid angle, is the angular space subtended at the center of a sphere by a portion of its surface equal to its radius squared. An entire sphere includes 12.5664 steradians and a hemisphere 6.2832 steradians. The symbol for luminous flux is F, that for luminous intensity I, and that for steradians ω. The following relations hold:

Flux in any solid angle,	$F = \int I\, d\omega;$
Total flux from source,	$F_s = 12.5664\, I_{ms};$
Flux in lower hemisphere,	$F_{lh} = 6.2832\, I_{mlh};$
Flux in upper hemisphere,	$F_{uh} = 6.2832\, I_{muh};$
Flux in any zone	$F_z = \omega_z\, I_{mz};$

where the I's have the designations given in the following paragraph.

LUMINOUS INTENSITY, commonly termed candle-power, denotes the solid angular density of light flux emitted in the direction considered, or

$$I = \frac{dF}{d\omega}.$$

Although luminous intensity refers in the strict sense to a single direction, mean intensities within certain limits are widely used. The following designations are employed in this article and also the articles on *Illumination, Laws of*, and *Photometry*.

Mean horizontal intensity,	I_h.
Mean spherical intensity,	I_s.
Mean zonal intensity,	I_{mz}.
Mean upper hemispherical intensity,	I_{muh}.
Mean lower hemispherical intensity,	I_{mlh}.

International Candle. — The international candle is the official unit of luminous intensity in France, Great Britain and the United States. The Hefner unit, which is standard in Germany equals 0.9 international candle. For further discussion of photometric standards see *Photometry*.

Distribution Curves. — The luminous intensities at various angles about a light source are commonly represented by polar curves of horizontal and vertical

distribution. Caution should be observed in interpreting such curves. The mean horizontal intensity is equal to the mean polar radius of the curve of horizontal distribution. The mean polar radius and the inclosed area of the curve of mean vertical distribution are entirely lacking in significance. For methods of computing mean intensities from vertical distribution curves, see *Illumination, Laws of*.

Spherical Reduction Factor. — This factor is the ratio of the mean spherical intensity of an illuminant to its mean horizontal intensity.

ILLUMINATION denotes the density of light flux intercepted by a surface or traversing an area in space. The unit of illumination corresponds to unit flux per unit area and is commonly one lumen per square foot, or foot-candle. The metric unit of illumination is the meter-candle, or lumen per square meter, sometimes called the "lux." It has been proposed by Blondel to designate the unit of one lumen per square centimeter by the title "phot." One foot-candle is 10.764 meter-candles and one meter-candle is 0.0929 foot-candles.

For methods of measuring illumination see *Photometry;* for the calculation of illumination, see *Illumination, Laws of;* for values of illumination required for various purposes, see *Vision, Laws of.*

INTRINSIC BRILLIANCY OF COMMON ILLUMINANTS

Illuminant	Candles per sq. in.	Candles per sq. cm.
Crater, carbon arc	84,000	13,000
Magnetite arc	4,000	620
Nernst glower	3,010	470
Incandescent electric lamps:		
Tungsten, 1.25 watts per c-p	1,060	164
Graphitized carbon, 2.5 watts per c-p	750	120
Tantalum, 2 watts per c-p	580	90
Carbon, 3.1 watts per c-p	485	75
Carbon, 3.5 watts per c-p	400	63
Acetylene flame, 1-foot burner	53	8.2
Acetylene flame, 0.25-foot burner	33	5.1
Welsbach mantle	31	4.8
Welsbach mantle, mesh	56	8.7
Mercury arc	14.9	2.3
Kerosene flame	9.0	1.4
Gas flame	2.7	0.4
Frosted tungsten lamp, tip	1.67	0.26
Frosted tungsten lamp, side	6.0	0.93

SURFACE BRIGHTNESS OR INTRINSIC BRILLIANCY is the luminous intensity per unit area of a surface projected on a plane normal to the line of sight. It is measured in candles per square inch or per square centimeter of projected area. Let b denote surface brightness, S the area and θ the angle between the normal to the surface and the line of sight, then

$$b = \frac{dI}{dS \cos \theta}.$$

The specific luminous radiation is closely akin to surface brightness as it denotes the flux emitted per unit area. If the emission agrees with the cosine

law the specific luminous radiation E' and the surface brightness normal to the surface b_0, bear the relation

$$E' = \pi b_0.$$

The brightness of illuminated surfaces is conveniently expressed in lumens emitted per square foot, but this should be clearly distinguished from illumination, or lumens received per square foot.

Mean values of surface brightness or brilliancy of various illuminants are given in the preceding table (*Ives and Luckeish, Elec. W., Vol. 57*).

The presence in the field of view of illuminants of high brilliancy depresses to a marked degree the sensibility and acuity of vision. The upper limit of brightness consistent with best vision has been variously estimated between 4 and 7.5 candles per square inch. (*See Glare in article on Vision, Laws of.*) For method of measurement of surface brightness see Ives and Luckeish, *ref. cit.*

REFLECTION OF LIGHT. — Reflection is regular or diffuse according as the reflector is a polished surface or a matt. Regular reflection is characterized by equal angles of incidence and reflection, the formation of images and the invisibility of the reflecting surface. Diffuse reflection scatters light in all directions, produces no images and renders the reflecting surface luminous. The intensity of light reflected by a perfect matt surface varies in proportion to the cosine of the angle of departure from the normal, and the total flux reflected equals π times the normal intensity. However, some regular reflection always accompanies diffuse reflection and these laws can be applied only approximately. Fair diffusing plates can be prepared from barium sulphate, magnesium oxide or other white materials of extremely fine and even grain. Opal glass with both surfaces carefully depolished is fairly satisfactory for diffuse reflection and transmission of light. Wall coverings of paper, plaster, fabric, paint and kalsomine deviate considerably from the cosine law of diffusion and its corollary and caution must be observed invariably in applying these laws to calculations of illumination. All materials not white, gray or black are selective and vary in their reflecting power with the spectral composition of the light received.

The following approximate values of reflection coefficients have been collected from various sources and are useful in calculations dealing with reflected light.

Reflector	Coefficient	Reflector	Coefficient
Polished silver	0.92	Orange yellow paper	0.34
Silvered mirror	0.80	Light green paper	0.25
White blotting paper	0.80	Light pink paper	0.25
White bond paper	0.75	Light blue paper	0.18
White kalsomine	0.75	Medium blue paper	0.12
Flat white paint	0.66	Dull green paper	0.08
Chrome-yellow paper	0.62	Light red paper	0.10
Cream paper	0.56	Medium red paper	0.08
Flat cream paint	0.53	Medium brown paper	0.08
Flat ivory paint	0.50	Deep red paper	0.06
Light buff paper	0.45		

The above values refer to light having the spectrum of commercial incandescent illuminants. In general flat paints are slightly below papers of the same tone

in reflecting power, whereas glossy paints exceed papers by 0.10 to 0.15 on account of regular reflection.

The most satisfactory device for the measurement of coefficients of diffuse reflection is that described by Nutting, *Trans. Ill. Eng. Soc., Vol. 7, p.* 412.

ABSORPTION OF LIGHT. — Transmitting media possess qualities quite analogous to reflecting surfaces with respect to regular and diffuse transmission and selective absorption depending on color. The absorption of light in the varieties of glassware most used in the lighting art are approximately as follows (*see Trans. Ill. Eng. Soc., Vol. 6, p. 98*);

Kind of glass	Absorption in per cent	Kind of glass	Absorption in per cent
Clear	5–12	Ground	20–30
Light sand blast	10–20	Medium opalescent	25–40
Alabaster	10–20	Heavy opalescent	30–60
Canary	15–20	Flame	30–60
Light blue alabaster	15–25	Signal green	80–90
Heavy blue alabaster	15–30	Ruby	85–90
Ribbed	15–30	Cobalt blue	90–95
Opaline	15–40

[W. E. WICKENDEN.]

PHOTOMETRY. — (*See also Illumination, Laws of; Vision, Laws of; for definitions of quantities and symbols see Photometric Quantities.*) Photometry is the science of light measurement. Its chief aspects are the determination of (*a*) the intensity of light sources in definite directions, (*b*) mean vertical light distribution, (*c*) the mean intensity and light flux emitted within specified limits of distribution, (*d*) the illumination of surfaces, (*e*) the reflecting properties of surfaces and (*f*) the analysis of the color of light. Its methods are essentially visual and consist in equating the brightness of two diffusing surfaces. As an instrument of physical measurement the eye lacks precision as an estimating device, but serves well in the judgment of equality. Photometric devices are of four general types, according to the method of comparison employed, viz., (1) by equality of brightness of two surfaces visible simultaneously, (2) by equality of contrast between two pairs of surfaces differing slightly in brightness, (3) by the disappearance of flicker when two surfaces are viewed in rapid alternation, and (4) by acuity of vision. The latter process does not admit of precision and is used only for rough comparisons.

Methods of Obtaining Photometric Balance. — The methods of obtaining photometric balance are: (1) varying the distance of one or both light sources from the surfaces compared, according to the law of inverse squares (*see Illumination, Laws of*); (2) varying the angle of incidence of light according to the cosine law (*ibid*); and (3) varying the proportion of light received by means of a sector disk or slit and collimator. In cases (1) and (2), given two diffusing surfaces illuminated to equal brightness b by respective light sources of intensities I_1 and I_2; the reflection or transmission coefficients of the surfaces as K_1 and K_2; the angles of incidence as α_1 and α_2; and the distances from the light sources d_1 and d_2 respectively; then if $\alpha_1 = \alpha_2$ and $K_1 = K_2$ and I_2 is the known intensity of a standard lamp,

$$I_1 = \frac{I_2 d_1^2}{d_2^2}.$$

If α_1 and α_2 or K_1 and K_2 differ slightly, a sensibly correct result is obtained by interchanging the light sources for half the observations and using the mean distances in the inverse square relation.

STANDARD LAMPS. — A primary standard possesses two essential qualities, definiteness and reproducibility from specifications. None of the existing standards of luminous intensity meet both requirements. Of the flame standards, the Hefner and pentane lamps are approximately reproducible and fairly definite with standard atmospheric conditions and fuel. The incandescent electric lamp is capable of definite calibration, but is not strictly reproducible. The present unit of luminous intensity, the international candle, is derived from the mean intensity of a group of incandescent electric lamps maintained by the U. S. Bureau of Standards, in coöperation with similar custodians in France and Great Britain.

Hefner Standard. — The Hefner standard which is the official standard of Germany and which has been extensively used in the United States, is a wick lamp burning amyl acetate of definitely specified chemical and physical properties. Its standard intensity is 0.9 international candle. Expressing the actual intensity as I, corrections for various atmospheric conditions are made as follows:

For variations from the standard flame height of 40 mm.

$$I = 1 + 0.025\,(h - 40) \text{ or } I = 1 - 0.034\,(40 - h)$$

for heights greater or less than 40 mm. respectively, where h is the flame height in millimeters. For barometric variations

$$I = 1 + 0.00011\,(b - 760),$$

where b is the barometric pressure in millimeters. For atmospheric humidity

$$I = 1.049 - 0.0055\,x,$$

where x signifies the liters of water vapor per cubic meter of air at 760 mm. and free from CO_2.

For atmospheric vitiation by CO_2

$$I = 1.012 - 0.0072\,y,$$

where y signifies the liters of CO_2 per cubic meter of dry air.

The objections to the Hefner standard are its low intensity, its reddish color, its flabby flame and its sensitiveness to variation in flame height. The element of uncertainty associated with it is at best not less than 2 per cent.

Pentane Standard. — The pentane standard, as represented by the Vernon-Harcourt type, is essentially an argand burner supplied with pentane-air gas and preheated air. The fuel is formed by passing air over pentane in a saturator box subdivided by baffles. The burner is surmounted at a height of 47 mm. by a cylindrical chimney. An annular chamber surrounding the chimney supplies the interior of the flame with preheated air. The flame is shielded from drafts by a conical, blackened hood having a slit at one side through which the flame is exposed. The chimney is fitted with a mica window showing a gauge line to which the flame height is closely adjusted. Under standard atmospheric conditions, viz., a barometric pressure of 760 mm. and a humidity of 8 liters of water vapor per cubic meter of air the flame should have a horizontal intensity of 10 candles. Experience indicates, however, that it is usually less by 2 to 4 per cent and that it is desirable to calibrate the lamp against a more definite standard. Variations from the above standard atmospheric conditions may be corrected by the equation:

$$I = I_n\,[1 - 0.00567\,(e - 8) + 0.0006\,(b - 760)],$$

where I is the actual intensity, I_n the standard intensity, e the liters of water vapor per cubic meter of air and b the barometric height.

The color and intensity of the flame are convenient for practical purposes, especially for the measurement of the illuminating power of gas. An added advantage in the testing of luminous flames of all sorts resides in the fact that their intensities are affected by atmospheric variations in a manner corresponding quite closely to the changes in the pentane lamp, whereby somewhat troublesome corrections are avoided.

Carcel Lamp. — The Carcel lamp is the recognized standard of luminous intensity in France. It has a central-draft ring burner fitted with a wick of the light-house type burning colza oil. Its standard intensity is 9.61 international candles.

Standard candles are now discredited for all accurate work, though still used extensively in the routine testing of gas.

Incandescent Electric-lamp Standard. — The incandescent electric lamp is superior to all other working standards where corrections for flame luminosity due to atmospheric variations are not required. Carefully selected carbon-filament lamps aged by burning until the hot resistance is constant maintain their candle-power sensibly unchanged for a period of 100 hours or more. With the most precise photometric apparatus such lamps may be standardized

with the mean error of any single determination not exceeding 0.2 per cent. Lamps are standardized for use in a fixed position or in rotation about the principal axis. No difference exists between the precision of the two methods. Lamps are standardized in terms of a definite voltage, current or power consumption, of which the first method is the most common. Lamps standardized for a definite voltage or current require more careful aging and are somewhat less permanent than those standardized for a definite power. Current and voltage values, however, are more readily determined and checked with precision by the use of the potentiometer. It is desirable to have lamps standardized in terms of both voltage and current for the constancy of the lamp can be relied upon as long as both standard conditions exist simultaneously. Carbon filament lamps at 4 watts per candle are most widely used as standards, though the limited experience to date with metal filament lamps shows them to be quite satisfactory. The color value at 4 watts per candle is distinctly more red than illuminants in general use. It is best to keep on hand a group of well-seasoned lamps of all commercial types and to select from these the most appropriate working standard for calibration against the primary carbon standard, so that the latter is used only for checking.

Other Standards have had a very limited use. Among these are the acetylene flame; the Methven screen, which is essentially a sharply-defined portion of a luminous gas flame, calibrated against a primary standard; and the Elliot lamp, which is a kerosene lamp of the student type having a limited portion of its flame exposed by a screen. The utility of these standards is largely in the routine testing of gas.

Relations of Luminous Standards. — The relative intensities of the several standards under standard conditions are given in the following table:

	International candle	Hefner	10-c-p. pentane	Carcel	Bougie decimale	English candle	German candle
International candle	1.00	1.11	0.10	0.104	1.00	0.96	0.95
Hefner	0.90	1.00	0.09	0.0936	0.90	0.864	0.855
10-c-p. pentane	10.00	11.11	1.00	1.04	10.0	9.6	9.5
Carcel	9.61	10.66	0.96	1.00	9.6	9.24	9.19
Bougie decimale	1.00	1.11	0.10	0.104	1.00	0.96	0.95
English candle	1.04	1.154	0.104	0.1	1.04	1.00	0.98
German candle	1.055	1.17	0.105	0.109	1.055	1.02	1.00

SIGHT BOXES. — A photometric sight box consists of two diffusing surfaces and accessories to facilitate the comparison of brightness. The types described following are of greatest utility.

Bunsen Sight Box. — The bunsen screen is a disk of white diffusing paper, a well-defined region of which is made translucent by impregnation with paraffine or other material. The disk is set transversely in a sight box of blackened interior, as shown on the plan in Fig. 1. Light from the sources to be compared enters the apertures A–A, and falls normally on the disk surfaces. Dihedral mirrors M_1 and M_2 enable both sides of the disk to be viewed at the sight tube T. The opaque portion of the disk reflects diffusely, while the translucent region partially reflects and partially transmits the light received. A photometric balance exists when the two sides of the disk appear alike. If both lights are alike in color and the absorption of both regions of the disk is equal, the boundary disk appears and both sides appear uniformly bright. With unequal ab-

sorption, balance exists when equal contrast exists between the opaque and translucent regions on both sides of the disk. The contrast principle is of distinct advantage with slight color differences. The sensitiveness of the screen depends largely on the definition of the boundary of the impregnated portion.

Leeson Disk.—This is a useful modification of the Bunsen type built up by pasting opaque paper disks with accurately matched star-shaped apertures on the two sides of a disk of translucent paper. By a careful selection of the materials the disk may be made to embody either the equality-of-brightness or the equality-of-contrast principle. The paper used should agree closely with the cosine law of diffusion.

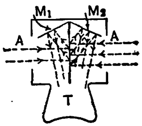

Fig. 1.

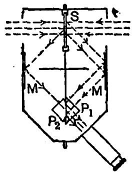

Fig. 2.

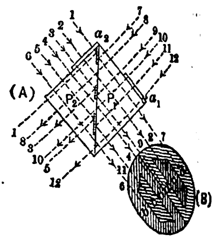

Fig. 3.

Lummer-Brodhun Sight Box.—The plan of this box is shown in Fig. 2. An opaque diffusely-reflecting screen S receives light from the sources to be compared and reflects it along the paths indicated by aid of the mirrors M–M and the prisms P_1–P_2. The prisms present to the eye a composite field in which the brightness of the two sides of S can be conveniently compared. Fig. 2 also shows the arrangement for equality-of-brightness working. The prisms are in optical contact over an elliptical portion of their hypotenusal faces, and the remainder of one is cut away. The central portion of the field is illuminated by direct transmission through the contact area, the outer portion by total reflection from the face of the uncut prism.

For equality-of-contrast working the arrangement of the prisms is as shown in Fig. 3. The hypotenusal face of P_2 is recessed over the area shaded in (B). That of P_1 is plane. Two thin glass absorbing strips a_1 and a_2 are set before the faces of P_1 and P_2 as shown in the plan (A). By tracing the several paths indicated it is seen that the field has the appearance of (B) and that the regions shaded are darkened by the absorption of light in a_1 and a_2. In a state of balance b and d appear equally bright and c and e equally dark in contrast. The degree of contrast created by a_1 and a_2 should be about 3.5 per cent for the best sensitiveness. Accuracy of adjustment and cleanliness of all parts are essential in photometers of the Lummer-Brodhun type.

Comparison of Bunsen, Leeson, and Lummer-Brodhun Boxes.—Bunsen, Leeson and Lummer-Brodhun sight boxes should be so mounted as to permit the complete reversal of the optical system about its axis of symmetry in order that optical asymmetry may be corrected as explained above. The Bunsen and Leeson types are binocular and therefore less fatiguing in a long series of observations than the monocular Lummer-Brodhun type. Furthermore, they are the more readily balanced with slightly flickering light. The Lummer-Brodhun contrast type excels in sensitiveness and general utility with steady lights of equal and slightly dissimilar color.

Flicker Photometer. — The flicker photometer affords the most reliable means of comparing light sources of distinctly unlike color. A field of view alternately illuminated by two such sources displays a flickering appearance which may be due to color dissimilarity or to difference in brightness. Above a moderate rate of alternation the color sensations blend and the disappearance of flicker is a true indication of equal brightness, as conclusively established by Ives, who recommends the following conditions as suited to the best precision: (*a*) a field illumination of 25 meter-candles; (*b*) a photometric field of 2 in. diameter; and (*c*) a background field about 25 in. in diameter surrounding the photometric field and about equal to it in brightness. The latter provision, though not essential to precision, is an aid to comfort.

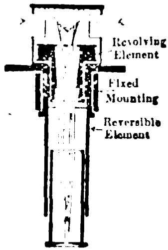

Fig. 4.

Bechstein Flicker Photometer (Fig. 4). — This photometer employs a train of lens and prism oscillating before a fixed diffusing wedge. The field of view consists of a circle and ring, alternately illuminated by the respective sides of the wedge as the lens system revolves. The highest sensitiveness exists at the lowest speed at which the flicker can be made to disappear.

Wild Flicker Photometer (Fig. 5). — The Wild flicker photometer is the simplest of this class. It consists of a disk *D* of white diffusing paper, one-half of which is made translucent by impregnation. This disk is revolved about an axis slightly at one side of the path of light and a mirror *M* reflects one side of the disk to the sight tube *T*. A high degree of precision is claimed by Wild for this device.

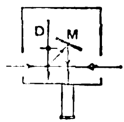

Fig 5.

Color-equalizing Screens. — The simplest method of comparison for lights of dissimilar color is to employ a Lummer-Brodhun photometer in connection with a set of glass screens of graded tints, selecting one which renders the light of the standard lamp equal in color to that of the lamp under measurement. The absorption of each screen for the light of the standard lamp must be determined by means of the flicker photometer, but the inconvenience of using the latter instrument is limited to the process of calibration.

Sector Disk. — The sector disk affords a most convenient means of reducing the intensity of the light received from an illuminant on the photometric screen. It consists of two or more disks with sector apertures revolving on a common axis. By advancing one disk with respect to the other the net aperture may be altered at will. By Talbot's law the intensity of transmitted to incident light equals the ratio of the total angular opening to 360 degrees. The sector disk has the advantage over other absorbing media in that it is adjustable, is not affected by time, and is independent of color.

Photometric Bar. — The devices above described are best suited for use in connection with a photometric bar or bench, which should be level and straight, and preferably greater than 100 inches in length. A plan of the layout is shown in Fig. 6. For convenience the sight box and at least one of the lamps should be mounted on movable carriages. The bench should be provided with a series of screens *D* of dead black material having graded apertures along the photometric axis and with solid screens at the ends. These screens should completely occlude from the sight box all extraneous light, and should protect the eye of the operator from the direct light of the lamps. If these conditions are met the photometric

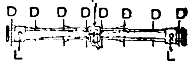

Fig. 6.

room need not be blackened. The sight box should have a dark background, however, and all light in the room should be well diffused. The bar should be provided with a scale of equal divisions and a scale reading directly the ratio of the inverse squares of the distances from the ends of the bar. For use with a standard lamp of definite value in a fixed position a direct reading scale of candle-power is readily obtained from the ratio scale.

Connections for Testing Incandescent Electric Lamps.—In testing incandescent electric lamps the effects of voltage fluctuation must be reduced to a minimum. A storage battery or special generator of very close regulation should be employed if possible. The effect of variations in line voltage is minimized by the method of connection shown in Fig. 7. L_1 and L_2 are two lamps under test. R_1, R_2 and R_3 are rheostats capable of fine adjustment. V is a voltmeter or potentiometer. S_1, S_2 and S_3 are instrument switches. The voltmeter may be made to measure the voltage at L_1, at L_2 or the difference between the two. The former connections are for initial adjustments and checks, the latter for holding the proper relative voltages.

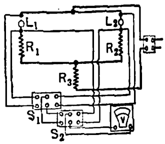

Fig. 7.

Manipulation of Photometric Bar. — Direct comparison between the test lamp and the standard may be made with the two in fixed positions by moving the sight box to a point of balance. In this case half the observations should be made with the sight box reversed. For the substitution method a fixed socket is provided at one end of the scale. The second socket and the sight box are on movable carriages coupled at a fixed distance. A well-seasoned lamp is placed in the movable socket and adjusted to a suitable voltage, which is subsequently held constant. The standard lamp is placed in the fixed socket and a balance secured by setting the movable carriages. The standard lamp is then removed and test lamps substituted in turn, a balance point being observed for each. The intensity of each test lamp equals that of the standard multiplied by the direct ratio of the squares of their distances from the screen at the times of balance. Reversals are unnecessary in the substitution method. The comparison lamp should be checked against the standard at intervals.

MEASUREMENT OF PHOTOMETRIC DISTRIBUTION.—Mean horizontal intensity is measured with the lamp rotating about its vertical axis. Special mountings, driven by motor or hand wheel, are provided for this purpose. Rotators are made universal by provision for the turning of the lamp by definite angular steps about its luminous center in a vertical plane including the photometric axis. The speed of horizontal rotation should be only sufficient to equalize differences in intensity.

Mirror Rotators. — In testing the light distribution of arcs, heavy reflector units, gas lamps, etc., which must remain in an upright position, mirror rotators are generally employed to direct the light from any desired vertical angle toward the photometer. A three-mirror device is shown schematically in Fig. 8. A two-mirror arrangement could also be used. In either case the lamp remains stationary, or is revolved about its vertical axis only, while the mirror system is turned by steps about the photometric axis. Numerous other devices for this purpose are described in standard works on photometry.

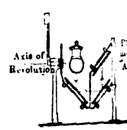

Fig. 8.

INTEGRATING PHOTOMETERS. — An integrating photometer enables the measurement of mean spherical or mean hemispherical intensity, or of the total flux of light from an illuminant, to be made by a single observation.

Ulbricht Integrating Sphere. — As shown schematically in Fig. 9, this apparatus consists of a hollow sphere whose inner surface is coated with a white material giving approximately true diffusion. A window of milk glass is placed in its horizontal axis. With a true spherical diffusing surface the light of an illuminant within the sphere is distributed as two components, viz., direct light, giving an intensity at any point on the surface according to the inverse square and cosine laws, and reflected light, which tends to spread itself uniformly over the entire surface if none is absorbed by obstructions. If then the direct light is screened from the window and it receives only the reflected component its brightness viewed externally is proportional to the total light flux emitted within the globe. The arrangement indicated is well adapted to a substitution method in which the errors due to non-sphericity, imperfect diffusion and to absorption in screens and lamps are minimized as much as possible. The calibrating lamp, whose mean spherical intensity is known, is first lighted and the resulting brightness of the window measured by a photometer. The calibrating lamp is then extinguished and the test lamp lighted, when a similar observation is made. The mean intensity of the test lamp equals that of the standard lamp multiplied by the ratios of the observed brightnesses of the window. A sphere intended for use with arc lamps and other large units should be not less than 5 feet in diameter; for work with incandescent lamps the sphere may be about 2 feet in diameter. The screens should be no larger than necessary to protect the window from direct light and should be coated with the same material as the spherical surface. For convenience the sphere may be divided vertically and at least one-half mounted on wheels. A removable circular section may be provided at the top. A thick paste of barium sulphate and zapon lacquer is largely used for the interior coating. The sphere is well adapted to the photometry of large and asymmetrical light sources. It is not a highly accurate device, but the final error involved need not exceed 5 per cent.

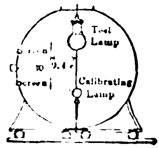

Fig. 9.

PORTABLE PHOTOMETERS. — Weber Photometer. — Portable photometers exist in great variety and have for their purpose the measurement of illumination and of the intensity of light sources in place. The great majority are modifications of the Weber photometer, shown schematically in Fig. 10. This comprises two cylindrical tubes of blackened interior, one fixed and the other attached to it at right angles by means of a sleeve to allow rotation. A Lummer-Brodhun prism device is placed at the junction of their axes, and permits the brightness of two translucent glass plates P_1 and P_2 to be compared at the eyepiece E. P_1 is illuminated by an external source L_1 at a distance d_1. P_2 is movable along the tube by a knurled head and is illuminated by a small standard lamp L_2 mounted in a convenient housing. Assuming both plates to be illuminated by light incident normally at a state of balance, then

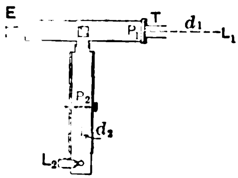

Fig. 10.

$$I_1 = \frac{I_2 T_2}{T_1} \times \frac{d_1^2}{d_2^2},$$

where T_1 and T_2 are the respective transmission coefficients of the two plates. A calibration for intensity measurements is readily obtained by the use of a standard lamp as I_1, and by observing the scale readings d_2 giving a balance with various values of d_1, keeping I_2 constant.

Two methods are available for the measurement of illumination. In the first the terminal tube T is removed and a flush test plate of depolished milk glass

fitted in its place. This test plate is placed in the position where the illumination is to be tested and the instrument balanced as usual.

For the second method of illumination measurement the terminal tube is not removed, but the plate P_1 is omitted. A large, white, diffusely reflecting card is placed in the position where the illumination is to be tested and the tube T pointed in its direction so that the entire cone of light entering T arises from the test plate. So long as this condition is met the inclination and distance of T is not important.

The first method is preferable where it is possible to make the attached test plate coincide with the position of the test. In the second method it is difficult to avoid interference with light which should reach the test plate.

Sharp-Millar Photometer. (Fig. 11.) — This photometer is a modified Weber instrument which is extensively used in America. It comprises an elongated wooden box divided into two compartments, one of which contains a fixed Lummer-Brodhun photometric cube and the other a lamp carriage movable along the box by turning a knurled head H. Observations are made at E at one side of the box. The two compartments are separated by a milk glass window whose brightness is balanced against illumination from an outside source admitted through an elbow tube T. Stray light in the lamp compartment is screened from this window by a series of diaphragms with central apertures. The elbow tube T is fitted on a collar and may be turned to any desired inclination. At the elbow is a circular, reversible plate one side of which is a mirror for measurements of illumination and the other a white diffusing surface for measurements of candle-power. In the former case the end of the tube is fitted with a flush plate of depolished milk glass. The range of the photometer is controlled by a pair of glass absorbing screens mounted in the compartment with the Lummer-Brodhun cube. These plates are respectively of high- and low-absorbing power. They may be turned so that either one may be used to reduce the illumination of either part of the field. But one may be employed at a time. In this way a range from 0.004 foot-candle to 2000 foot-candles may be secured. In the most recent design the need of a voltmeter or ammeter to keep the standard lamp constant is obviated by a small Wheatstone bridge arrangement with a telephone receiver, whereby the lamp may be kept at constant hot resistance. The Sharp-Millar photometer may be used with a detached test plate similar to that described for the Weber photometer.

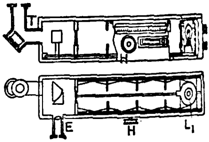

Fig. 11.

COLORIMETRY. — The Ives colorimeter is an instrument for tri-chromatic color analysis. (*See Vision, Laws of.*) It consists essentially of an oblong box, at one end of which are placed four slits, one clear, and the three others equipped respectively with red, green and blue screens. By means of levers the openings of the three colored slits can be altered to read by scales from 0 to 100. By rotating a wheel of lenses the three colors are mixed. The observer views a divided field, one part consisting of the mixture of the three primary colors and the other of the color to be matched as viewed through the clear slit. To make a measurement, the three colored slits are opened until white is matched, and the scales are set to read 100 for each color. Then any color matched by moving the levers can be read off in terms of the per cent of red, green and blue necessary to match white. The precision of the instrument is from 2 to 5 per cent under favorable conditions.

REFLECTING POWER OF SURFACES. — See section on *Reflection of Light* in the article on *Photometric Quantities*.

PRECAUTIONS IN PHOTOMETRIC OBSERVATIONS. — The eyes of the observer should be constantly shaded from bright light to maintain their sensitiveness in a state of dark adaptation. For best photometric sensibility a screen illumination of about 2 foot-candles is desirable. At low intensities the Purkinje effect (*see Vision, Laws of*) may prove disturbing. The precision of photometric settings may often be improved by a process of narrowing down between points equally out of balance. Many good photometricians reject their first observation in a set as untrustworthy. As the best conditions cannot reduce the uncertainty of observations below 0.2 per cent (in many cases it is 3 per cent or more) not more than three figures in the result are significant. A photometer bar should be at least 100 inches long for good results with ordinary illuminants. The distance from a large unit to the screen should not be less than 10 feet if the inverse square law is to be applied.

The voltage of electric lamps, or current, in the case of series lamps, should be measured by the most accurate device obtainable. In life tests of incandescent lamps exact regulation of voltage is of the utmost importance and a sensitive, automatic regulator is most desirable. In measurements of illumination by portable photometers the sources of error to be guarded against are: occlusion of light from the test plate by observer or instrument, uncertainty of standard lamp due to poor electrical regulation, faulty diffusion by the test plate, and low sensibility and Purkinje effect in weak fields. In tests of illuminants in place, the voltage, current or power, or the gas consumption and pressure should be ascertained and recorded if possible. In tests of gas illuminants the volume consumed should be reduced to the corresponding volume at a temperature of 60° F., and a barometric pressure of 30 inches.

[W. E. WICKENDEN.]

PI (π), VALUE OF. — The letter π is used to represent the ratio of the circumference of a circle to its diameter; it is an incommensurable quantity. Its value is 3.14159265. . . . The value 3.1416 is sufficiently accurate for all ordinary purposes, and for rough calculations the value 22/7 is convenient. The following factors frequently occur:

$\pi = 3.14159$	$\frac{\pi}{4} = 0.785398$	$\frac{1}{2\pi} = 0.159155$
$2\pi = 6.28319$		
$3\pi = 9.42478$	$\frac{\pi}{6} = 0.523599$	$\frac{1}{4\pi} = 0.079578$
$4\pi = 12.56637$		
$\frac{\pi}{2} = 1.57080$	$\frac{4\pi}{3} = 4.18879$	$\pi^2 = 9.86960$
		$\pi^3 = 31.00628$
$\frac{\pi}{3} = 1.04720$	$\frac{1}{\pi} = 0.318310$	$\sqrt[2]{\pi} = 1.77245$
		$\sqrt[3]{\pi} = 1.46459$

PIPES AND PIPING. — (*See also Boilers; Electrolysis of Grounded Structures; Hydraulics, Principles of; Power Stations; Valves.*) In the following table is given a list of the metals ordinarily used for steam, gas and water pipes, together with their average weight per cubic inch, their tensile strength and the expansion per 100 feet for various temperature differences. The expansions are based on data given in Gebhardt's *Steam Power Plant Engineering*.

TENSILE STRENGTH, WEIGHT AND EXPANSION OF PIPE MATERIALS

Material	Lb. per cu. in.	Tensile strength, lb. per sq. in.	Expansion (in. per 100 ft.) Temp. rise above 60° F.				
			100°	200°	300°	400°	500°
Brass, wrought	0.30	50,000	1.15	2.41	3.80	5.38	7.11
Copper, wrought	0.32	30,000	1.08	2.26	3.56	5.05	6.66
Iron, cast	0.26	18,000	0.72	1.50	2.38	3.36	4.44
Iron, wrought	0.28	50,000	0.79	1.65	2.61	3.70	4.89
Lead	0.41	1600 to 2400	....	....	....	....	....
Steel, mild	0.28	65,000	0.79	1.65	2.61	3.70	4.89

Of the above materials mild steel is most widely used for general work. Wrought iron is more expensive but is sometimes preferred. Cast iron is largely used for water service and sanitation, and also to a limited extent where many connections are required, due to the fact that the flanges are cast with the piece. Copper and brass are used only to a limited extent, on account of their high cost. Lead is used to a limited extent for water pipes. Fittings are usually made of brass, cast iron, malleable iron or pressed steel. Wooden stave pipe is also much used in the western part of this country for water supply and power.

DIMENSIONS AND WEIGHT OF COMMERCIAL PIPE. — The size of iron and steel pipes is usually specified in terms of the "nominal" inside diameter. The actual inside diameter is usually greater than the "nominal," the percentage difference being the greatest for small sizes. The thickness of wall and weight per lineal foot of a given size of pipe varies over a considerable range, due to processes of manufacture. Manufacturers specify that "full weight" pipe may have a variation of from 5 per cent above to 5 per cent below nominal or table weight, but "merchant pipe," which is the ordinary pipe carried by jobbers and manufacturers, is almost invariably from 5 to 10 per cent under the nominal weight.

In drawing specifications for pipe, engineers should be careful to state what grade of pipe is desired, whether "merchant," full weight, or extra strong, and in the case of cast-iron pipe the class according to the table on the next page.

Cast-iron Pipe. — The following dimensions and weights are taken from the catalogue of the U. S. Cast-iron Pipe and Foundry Co. (1908). The weights are figured on the basis of a pipe length of 12 feet, and include proportional part of weights of standard sockets.

DIMENSIONS AND WEIGHT OF CAST-IRON PIPE

Nominal inside diam., in.	Class A		Class B		Class C		Class D	
	Thickness, in.	Lb. per ft.	Thickness, in.	Lb. per ft.	Thickness, in.	Lb. per ft.	Thickness, in.	Lb. per ft.
3	0.39	14.5	0.42	16.2	0.45	17.1	0.48	18.0
4	0.42	20.0	0.45	21.7	0.48	23.3	0.52	25.0
6	0.44	30.8	0.48	33.3	0.51	35.8	0.55	38.3
8	0.46	42.9	0.51	47.5	0.56	52.1	0.60	55.8
10	0.50	57.1	0.57	63.8	0.62	70.8	0.68	76.7
12	0.54	72.5	0.62	82.1	0.68	91.7	0.75	100.0
14	0.57	89.6	0.66	102.5	0.74	116.7	0.82	129.2
16	0.60	108.3	0.70	125.0	0.80	143.8	0.89	158.3
18	0.64	129.2	0.75	150.0	0.87	175.0	0.96	191.7
20	0.67	150.0	0.80	175.0	0.92	208.3	1.03	229.2
24	0.76	204.2	0.89	233.3	1.04	279.2	1.16	306.7
30	0.88	291.7	1.03	333.3	1.20	400.0	1.37	450.0
36	0.99	391.7	1.15	454.2	1.36	545.8	1.58	625.0
42	1.10	512.5	1.28	591.7	1.54	716.7	1.78	825.0
48	1.26	666.7	1.42	750.0	1.71	908.3	1.96	1050.0
54	1.35	800.0	1.55	933.3	1.90	1141.7	2.23	1341.7
60	1.39	916.7	1.67	1104.2	2.00	1341.7	2.38	1583.3
72	1.62	1283.4	1.95	1545.8	2.39	1904.2	....	......
84	1.72	1633.4	2.22	2104.2	....	......	....	......

The safe working pressures recommended for the four classes are:

SAFE WORKING PRESSURES, CAST-IRON PIPE

Unit of Pressure	A	B	C	D
Pounds per square inch........	43	86	130	173
Head of water, feet............	100	200	300	400

Welded Pipe. — The first table following is based on Briggs' Standard for sizes up to 10 inches, and upon the National Tube Co's Standard above 10 inches (1910). Weights per foot, up to and including 15 inches internal diameter, are based upon a length of 20 feet including the coupling; weights given for larger sizes are for plain end pipe.

The second table gives the dimensions of "Extra Strong" and "Double Extra Strong" welded tubes (*National Tube Co., 1902*).

DIMENSIONS AND WEIGHT OF WELDED PIPE

Size, nominal internal diam., in.	Diameter in inches		Thickness of metal, in.	Number of threads per in.	Weight of pipe per lin. ft., lb.
	Actual external	Approx. internal

Riveted Pipes. — Large pipes are frequently made of sheets of boiler steel with riveted joints, with longitudinal, circumferential or spiral seams. The following tables give the necessary data regarding dimensions, rivets, etc. The first table is taken from a catalogue of the Abendroth & Root Mfg. Co.

SHEET IRON AND RIVETS REQUIRED FOR RIVETED PIPES

No. sq. ft. of iron required to make 100 lin. ft. punched and formed sheets when put together			Approx. No. of rivets 1 in. apart required for 100 lin. ft. punched and formed sheets	No. sq. ft. of iron required to make 100 lin. ft. punched and formed sheets when put together			Approx. Wooden Stave Pipes are usually built up in place. Staves of redwood, fir, yellow pine, and spruce are used. The staves range from 1¼ to 2½ inches in thickness and from 6 to 8 inches in width; these are held in place by steel bands ranging from ⅜ to ¾ inch in diameter. The interior surfaces of the staves wear smoother by the action of the flowing water and do not become fouled. Stave pipes have been installed in sizes ranging from 18 to 144 inches in diameter, and for heads up to 300 feet.

FORMULAS FOR WEIGHT, CIRCUMFERENCE, SURFACE, CONTAINED VOLUME AND SAFE PRESSURE. — Let

A = external surface per lineal foot in square feet,
C = external circumference in inches,
D = internal diameter in inches,
D_0 = external diameter in inches,
f = factor of safety,
H = safe head in feet of water,
P = safe pressure in pounds per square inch,
S = tensile strength in pounds per square inch,
T = thickness of wall in inches,
V = volume of contents (water, steam or gas) per lineal foot in cubic feet
w = specific weight of metal in pounds per cubic inch,
W = weight of metal per lineal foot in pounds.

Then

$$A = 0.262\,D_0, \qquad C = 3.14\,D_0, \qquad D_0 = D + 2T,$$

$$H = \frac{4.62\,ST}{Df}, \qquad P = \frac{2\,ST}{Df},$$

$$T = \frac{D_0 - D}{2} = \frac{DfP}{2\,S} = \frac{DfH}{4.62\,S},$$

$$V = 0.00545\,D^2, \quad W = 9.42\,w\,(D_0^2 - D^2) = 37.7\,wT\,(D + T).$$

The values of the specific weight w and tensile strength S are given in the table at the beginning of this article. The tensile strength of riveted pipe is about 70 per cent of the tensile strength of the metal.

PIPE FITTINGS. — For dimensions and weights of various pipe fittings see *Kent's Mechanical Engineers' Pocket Book*, pp. 196–207 (8th Edition). See also article in this book on *Valves*.

PIPE COVERINGS. — To prevent loss of heat by radiation, steam and feed-water pipes are usually protected with a cover, 1 inch or more in thickness,

of loose non-conducting material. About 3 B.t.u. per square foot per hour per degree difference in temperature is radiated from a bare pipe under ordinary conditions. By the use of any good commercial covering from 75 to 85 per cent of this loss may be prevented. Pipe covering is usually applied in sections, moulded to fit the pipe, and held in place by bands. The covering for fittings and valves is usually applied in plastic form.

FLOW OF WATER THROUGH PIPES. — The pressure required to force a stream of water through a pipe is usually expressed in terms of the height of a column of water which would produce a static pressure equal to this pressure. A pressure of

1 pound per square inch = 2.31 feet of water column,
1 foot of water column = 0.433 pound per square inch.

Friction and Velocity Head. — The head required to overcome the resistance of a pipe is called the "friction head," and for a given pipe and velocity of flow is proportional to the length of the pipe. The head required to overcome the resistance at the entrance to a pipe is called the "entry head;" in the case of long pipes the entry head is negligible in comparison with the friction head. In addition to these two heads, a certain pressure, and therefore a corresponding head, is required to produce any change in the velocity of flow, as, for example, when water enters a pipe from a reservoir. This velocity head is equal to $\frac{V_1^2 - V_2^2}{64.4}$, when the velocity changes from V_1 to V_2 feet per second. A decrease in velocity gives rise to a *negative* velocity head. In long pipes the velocity head is negligible.

Hydraulic Grade Line. — Imagine a horizontal line drawn over a pipe line from a reservoir, and let this horizontal line be at the same elevation as the surface of the reservoir. From each point of this horizontal line drop perpendiculars equal in length to the loss of head between this point and the reservoir. The locus of the foot of these perpendiculars is called the "hydraulic grade line." In a pipe leading from a reservoir no part of the length of the pipe should be above the hydraulic grade line. If the pipe has vertical curves, valves should be provided at the high points to permit the escape of the air which tends to collect at the top of such curves, otherwise the pipe may become "air-bound," i.e., water will not flow although the supply is higher than the outlet.

Formulas Connecting Velocity, Discharge, and Head. — Various formulas have been proposed to express the relation between velocity, discharge and head. Let

d = diameter of pipe in inches,
D = diameter in feet,
H = loss of head in pipe in feet of water,
L = length of pipe in feet,
p = loss of pressure in pipe in pounds per square inch,
Q = discharge in cubic feet per second,
V = velocity of flow in feet per second.

Unwin gives the following formula:

$$V = 4.012\sqrt{\frac{DH}{fL}},$$

where f is the coefficient of friction. This coefficient depends upon the smoothness and cleanness of the pipe and also upon whether the pipe is straight or

crooked, and upon the velocity. (*See Kent's Mechanical Engineers' Pocket Book.*) Rankine gives the following formula for f for smooth, clean, straight pipe:

$$f = 0.005\left(1 + \frac{1}{12\,D}\right).$$

This formula is approximate only, since it does not take into account the velocity of flow. It is sufficiently accurate, however, for velocities up to 6 feet per second.

Combining these two formulas the following are obtained:

$$V = 16.4\,d\sqrt{\frac{H}{L\,(d+1)}} = 25\,d\sqrt{\frac{p}{L\,(d+1)}},$$

$$V = 57\,D\sqrt{\frac{H}{L\,(D+0.083)}} = 87\,D\sqrt{\frac{p}{L\,(D+0.083)}},$$

$$Q = 0.00545\,d^2V = 0.089\,d^3\sqrt{\frac{H}{L\,(d+1)}} = 0.136\,d^3\sqrt{\frac{p}{L\,(d+1)}},$$

$$Q = 0.785\,D^2V = 44.7\,D^3\sqrt{\frac{H}{L\,(D+0.083)}} = 68\,D^3\sqrt{\frac{p}{L\,(D+0.083)}}.$$

When the pipe is not completely filled with water, the same formulas hold provided d and D are taken as 4 times the hydraulic radius. The "hydraulic radius" is defined as the ratio of the area of the cross section of the water to that portion of the perimeter of the pipe in contact with the water.

These formulas apply approximately to any kind of clean, straight pipe, provided the interior surface is smooth. The formulas involving the head H also apply approximately to any kind of liquid or gas, provided H is taken as the height of a column of the given liquid or gas which will produce a static pressure equal to the fall in pressure in the pipe. The coefficients in the formulas involving the drop of pressure p should then be multiplied by $\sqrt{\frac{62.4}{w}}$, where w = weight in pounds of 1 cubic foot of the given liquid or gas, and 62.4 = weight in pounds of 1 cubic foot of water.

These formulas are for *new, clean, straight pipes*. For cast-iron pipes that have been in service a number of years the loss of head will be larger on account of corrosion and incrustation, and the value of H in the formulas should be multiplied under average conditions by the factors opposite; but they must be used with much discretion, for some waters corrode pipes much more rapidly than others.

10 years	1.3
20 "	1.6
30 "	2.0
50 "	2.6
75 "	3.4

The same figures may be used for wrought-iron pipes which are not subject to a frequent change of water.

From the above formulas for velocity the loss in head due to pipe resistance is

$$H = \frac{LV^2\,(d+1)}{270\,d^2} = \frac{LV^2\,(D+0.083)}{3250\,D^2}.$$

William Cox (*Amer. Mach.*, 1893) gives the following formula for pipes over 6 inches in diameter:

$$H = \frac{L\,(V^2 + 1.25\,V - 0.5)}{300\,d}.$$

The Pelton Water Wheel Co. advocate the following formula for riveted pipe for pipes over 6 inches in diameter:

$$H = \frac{L(V^2 + 1.25 V - 0.5)}{250 d}.$$

Effect of Curves and Valves.—The resistance of curves and valves may be allowed for approximately by taking for L in the above formulas the actual length of the pipe plus a length equal to

$$\frac{kd^2}{d+1} \text{ feet, } \quad \text{or} \quad \frac{KD^2}{D+0.083} \text{ feet,}$$

for each curve or valve, where k and K have the following values:

	45° angle	90° angle	Gate valve	Globe valve	Angle valve
$k=$	0.8	4.2	0.8	8.1	12.4
$K=$	9	49	9	96	148

These coefficients are based on data given by Gebhardt (*Steam Power Plant Engineering*). Variations of 100 per cent or more from the valves given may be expected, depending on the radius of the bends and design of the valves.

Water-Hammer. — From the formula given by Prof. I. P. Church the pressure developed by the instantaneous closing of a valve in a water pipe is

$$P_i = \frac{63.5\, V}{\sqrt{1 + \frac{300{,}000\, d}{MT}}} \text{ pounds per square inch,}$$

where M = modulus of elasticity of the pipe material and the other symbols are as above.

FLOW OF AIR AND GAS THROUGH PIPES. — (*See also preceding section.*) Let

d = internal diameter of pipe in inches,
L = length of pipe in feet,
p = fall of pressure in the pipe in pounds per square inch,
Q = discharge in cubic feet per second,
V = linear velocity in feet per second,
w = weight of 1 cubic foot of air or gas in pounds.

Then from Unwin's formula, using the same coefficients as for the flow of water, *when the fall of pressure is small,*

$$V = 198\, d \sqrt{\frac{p}{wL(d+1)}}. \qquad (1)$$

$$Q = 1.08\, d^3 \sqrt{\frac{p}{wL(d+1)}}. \qquad (2)$$

For air: $\quad w = \dfrac{2.70\, P}{460 + t}$; for any other gas: $\quad w = \dfrac{2.70\, GP}{460 + t}$,

where P = absolute pressure in pounds per square inch and t = temperature in degrees F and G = the specific gravity of the gas referred to air as unity. For ordinary illuminating gas $G = 0.65$.

Various authorities give different values of the numerical coefficients in the formulas for V and Q (*see Kent's Mechanical Engineers' Pocket Book*). The values given above, which are the same as for the flow of water ($w = 62.4$), are sufficiently accurate for rough calculations. The formula for Q may also be written

$$Q = Cd^2\sqrt{\frac{dp}{wL}}, \tag{3}$$

where $C = 1.08\sqrt{\dfrac{d}{d+1}}$, corresponding to the coefficient 1.08 in equation (2).

C is frequently taken as unity for all sizes of pipes.

When the *fall of pressure is large*, the above formulas for Q give approximately the quantity per second at the *average* pressure in the pipe, provided the weight per cubic foot is taken corresponding to this *average* pressure. Or, putting P = the pressure in pounds per square inch at the *outlet* of the pipe, and w = weight per cubic foot at this pressure P, p being the fall in pressure, then the discharge in cubic feet per second at the pressure P is approximately (from equation 2)

$$Q = 1.08\,d^3\sqrt{\frac{p\,(P + 0.5\,p)}{PwL\,(d+1)}}.$$

For d large compared with unity, $\dfrac{d}{d+1}$ may be taken sensibly equal to unity, and this expression may be written

$$Q = 1.08\,d^2\sqrt{\frac{p\,(P + 0.5\,p)\,d}{PwL}}.$$

For $P = 14.7$ pounds per square inch, and $t = 60°$ F., then for air

$$Q_a = 1.02\,d^2\sqrt{\frac{p\,(P + 0.5\,p)\,d}{L}}, \text{ cubic feet per second,}$$

and for illuminating gas of 0.65 specific gravity,

$$Q_g = 1.26\,d^2\sqrt{\frac{p\,(P + 0.5\,p)\,d}{L}} \text{ cubic feet per second.}$$

Instead of the coefficients 1.02 and 1.26 the following values correspond to the coefficients in the formulas used by the authorities named:

	Instead of 1.02	Instead of 1.26
Wm. Cox (*Am. Mach.*, 1902)	0.95	1.18
J. E. Johnson (*Am. Mach.*, 1899)	0.96	1.19
E. A. Rix (*Pac. Coast Gas Assoc.*, 1905)	1.05	1.30

Effect of Bends, Valves, etc. — The Norwalk Iron Works Co. give the following table; radius of elbow and length of pipe are both expressed in terms of the pipe diameter:

Radius of elbow.........	5	3	2	1½	1¼	1	¾	½
Equivalent lengths of straight pipe.........	7.85	8.24	9.03	10.36	12.72	17.51	35.09	121.2

W. L. Saunders (*Compressed Air*, 1902) gives the following figures for the length of pipe in feet equivalent to each of the items listed:

Diam. of pipe, in..	1	1½	2	2½	3	3½	4	5	6	7	8	10
Globe valves.....	2	4	7	10	13	16	20	28	36	44	53	70
Elbows and tees..	2	3	5	7	9	11	13	19	24	30	35	47

FLOW OF STEAM. — The formulas given in the preceding section apply only approximately to the flow of steam. Putting v = volume of 1 pound of steam in cubic feet (*see tables under Steam*), the above formula for flow in cubic feet per second becomes

$$Q = 1.08\, d^3 \sqrt{\frac{vp}{L\,(d+1)}},$$

and the corresponding flow in pounds per second is

$$W = 1.08\, d^3 \sqrt{\frac{p}{vL\,(d+1)}}.$$

G. H. Babcock, in *Steam*, gives the flow in pounds per minute as*

$$W = 87 \sqrt{\frac{wpd^5}{L\left(1+\frac{3.6}{d}\right)}}.$$

The corresponding flow in cubic feet per second may be written

$$Q = 1.45\, d^3 \sqrt{\frac{p}{wL\,(d+3.6)}}.$$

For a given drop in pressure this formula gives a less flow for pipes under 2 inches in diameter and a greater flow for pipes over 2 inches in diameter than is given by the corresponding formula for air or gas.

Effect of Bends, Valves, etc. — According to Briggs the effect of each right angle bend is equivalent to increasing the length 40 diameters, and the effect of each globe valve is equivalent to increasing the length 60 diameters.

* w is pounds per cu. ft. at entrance pressure.

POLES FOR OVERHEAD LINES. — (*See also Cross Arms; Distribution Lines; Insulator Pins; Insulators; Transmission Lines.*) The following is a brief table of contents of this article:

Methods of Specifying Pole Dimensions. — A pole for supporting an overhead line is usually specified by its *total* or "nominal" length and by the diameter of its top; e.g., a 40-ft 7-in. top pole. When set, the distance a pole stands above the surface of the ground is less than the nominal length by the amount it sets in the ground. Poles are standard in lengths which are multiples of 5 feet. The ordinary range of length is from 30 to 60 feet.

The top of a pole is sometimes specified by inches circumference instead of by diameter. Poles are standard in diameters which are even multiples of one inch. The ordinary range of top diameter is from 7 to 8 inches except on the Pacific Coast, where from 8 to 10 inches is common.

Taper of Poles. — The taper of various kinds of poles, specified as the difference, measured in inches, between two circumferences 10 feet apart, is given as follows in *Forest Service Bull. No. 84:* Chestnut (Maryland), 3.8 to 4.0; Northern white cedar (Michigan), 5.2; Western yellow pine (California), 4.0; Lodgepole pine (Montana), 3.0; Loblolly pine (Texas), 2.4; Western red cedar (Washington), 3.5. Trees grown upon a high elevation have a greater taper in the trunk than trees grown lower down.

WOODS USED FOR POLES AND CROSS ARMS. — (Based on publication of the Forest Service, see *Bibliography.*) Of the timbers used for poles, chestnut and northern, southern and Idaho cedar easily rank first. Longleaf and shortleaf pine, red cedar, cypress, redwood, locust, catalpa and several of the oaks are used, but in much smaller numbers, and their employment is generally confined to the region of their growth. Still other timbers are used, but in numbers insignificant in comparison with those mentioned above.

For cross arms, longleaf, shortleaf and loblolly pines of the South and Norway pine of the North are most largely used, while the demand for cedar, cypress, spruce and red fir is but little less. Again, as in the case of pole timbers, a third group may be formed of those timbers used in small numbers and very locally.

In 1911, of the 3,418,020 poles used in the United States, 61.5 per cent were cedar, 20.4 per cent were chestnut, the remainder being oak, pine, cypress, etc.

Desirable Timber for Poles. — The several qualities which timber must possess to adapt it to use for poles are stated to be: Durability in contact with the soil, minimum weight, straightness coupled with relatively small size and little taper. The wood must be soft, so that the spikes of a climber may enter readily and at the same time it must have strength to support considerable

weight. These qualities are admirably combined in cedar and in juniper, which commercially is a cedar; no other woods possess so many.

Uncertainties in Names of Timber Trees. — The terms cedar, pine, etc., used in describing poles and cross arms and even the apparently more exact terms, such as white cedar, yellow pine, etc., each cover several kinds of trees and have different meanings in different localities.

There are at least eight pines (of the thirty-five native ones) in the market, some of which so closely resemble each other in their minute structure that they can hardly be told apart; and yet they differ in quality and should be used separately, although they are often mixed or confounded in the trade.

Referring to the use of yellow pine as the material for cross arms the Committee on Overhead Line Construction of the N. E. L. A., says: "Yellow pine is understood to cover what is commonly known as longleaf pine. It is understood that the term is descriptive of quality rather than of botanical species." Forestry Bulletin No. 10 states: "'Yellow pine,' is applied in the trade to all the Southern lumber pines; in the Northeast it is also applied to the pitch pine; in the West it refers mostly to bull pine. 'Yellow longleaf pine,' 'Georgia pine,' chiefly used in advertisement, refers to longleaf pine."

Timbers Ordinarily Used for Poles and Cross Arms. — The principal timber trees from which poles and cross arms are obtained are briefly described below in accordance with the names used in the publications of the Forest Service.

Chestnut. — Chestnut ranks next to the cedars in the quantity of poles used. The reported number purchased in 1909 was 608,000. The sapwood is very narrow, usually from about 1/8 to 3/8 of an inch wide. Chestnut is widely distributed throughout the entire Appalachian mountain region. A small territory embracing parts of Pennsylvania, Maryland, Virginia and West Virginia furnishes nearly all the chestnut poles. Chestnut is not so straight as cedar and is liable to be knotty. It has greater strength, but this advantage is more than counterbalanced by its greater weight, which prohibits long shipments.

Northern White Cedar or Arborvitæ. — This species is very commonly used for poles throughout the central and eastern portion of the United States. The principal source of supply is in the states bordering the Great Lakes. It makes a very desirable pole on account of its durability but is high-priced. The sapwood varies from 1/2 to 1 inch in thickness. A very large portion of northern white cedar poles have unsound butts. Northern white cedar, common in the northern woods of New England, New York and the Lake States, occurs as far south as North Carolina and Tennessee, but only in the mountains where the elevation is sufficiently great to permit northern species to thrive.

On account of its strength, lightness, durability and form it is the most desirable pole timber. Arborvitæ is extremely slow in growth. The sapwood zone is narrow at the butt and gradually widens as the top is approached. The average time it takes to produce a 30-foot arborvitæ pole is about 190 years.

Southern White Cedar. — The number of southern white cedar poles purchased in 1909 was 44,000. The woods known under the general name of "cedar" comprise a number of distinct species which differ in their durability, the white cedar of the southern swamps being somewhat less durable than the cedar of the Lake States. The sapwood, which is usually from 1/2 to 1 inch wide, decays very quickly. Southern white cedar, though sometimes found as far north as southern Maine, is of commercial importance chiefly south of Delaware and New Jersey.

Red Cedar. — A small to medium-sized tree scattered through the forests, or, in the West, sparsely covering extensive areas (cedar brakes). The

red cedar is the most widely distributed conifer of the United States, occurring from the Atlantic to the Pacific and from Florida to Minnesota, but attains a suitable size for lumber only in the Southern and more especially in the Gulf States.

Juniper. — The term Juniper is commonly used by telephone men for southern white cedar; the term also is applied to red cedar. Juniper poles come from Virginia, the Carolinas and other South Atlantic States.

Western Red Cedar. — The light and durable western red cedar is much used for poles on the Pacific coast and throughout the Northwest. Also it competes to a certain extent with northern white cedar in the East, its form and size making it especially desirable for the larger classes of poles. The principal points of production are northern Idaho and western Washington. The relative durability of western red cedar and northern white cedar under similar conditions is not known, and the testimony by pole users on this point is somewhat contradictory.

Cypress. — The cypress is a large deciduous tree, occupying much of the swamp and overflow land along the coast and rivers of the Southern States. Cypress is usually considered a durable wood, and the heartwood is, in fact, one of the most durable of our native species. The sapwood, however, decays quickly and this seriously weakens the pole. The width of the sapwood on pole-size trees is from 3/4 of an inch to 1 1/4 inches. Cypress frequently is too large for use as a pole and has greater value for lumber. Even when its general diameter is small enough the butt will often be so big that it adds too much weight.

Longleaf Pine. — Large tree; forms extensive forests and furnishes the hardest and strongest pine lumber in the market. Coast region from North Carolina to Texas. The longleaf pine is strikingly heavy, hard and resinous, and usually very regular and narrow ringed, showing little sapwood, and differing in this respect from the shortleaf pine and loblolly pine, which usually have wider rings and more sapwood, the latter excelling in that respect.

Shortleaf Pine. — Resembles loblolly pine; often approaches in its wood the Norway pine. The common lumber pine of Missouri and Arkansas, North Carolina to Texas and Missouri.

Loblolly Pine. — Large-sized tree; forms extensive forests; wider-ringed, coarser, lighter, softer, with more sapwood than the longleaf pine, but the two often confounded. This is the common lumber pine from Virginia to South Carolina and is found extensively in Arkansas and Texas, Southern States, Virginia to Texas.

This pine is not durable when used as a pole unless treated with preservatives, but because of its cheapness and ease of impregnation is very desirable if preservative treatment is contemplated. Its distribution, ease of reproduction and rapidity of growth insure a steady and cheap supply. When this timber is used it is necessary to treat the entire pole instead of only the butt, especially in the warmer and more humid localities of the South.

Norway Pine.—Large-sized tree; never forming forests, usually scattered or in small groves, together with white pine; largely sapwood and hence not durable. Minnesota to Michigan; also in New England to Pennsylvania. The Norway pine, which may be confounded with the shortleaf pine can be distinguished by being much lighter and softer. It may also, but more rarely, be confounded with heavier white pine, but for the sharper definition of the annual ring, weight and hardness.

Western Yellow Pine. — Western yellow pine is used for poles to a limited extent in certain parts of the Southwest, where the high cost of more

durable pole timbers makes it necessary to find a cheaper substitute. The life of this timber, untreated, is very short. In the upper part of the San Joaquin Valley of California, where a study of this species was made, untreated pine poles last only two or three years; but since the wood when not exposed to the soil is fairly durable, it is believed that a butt treatment with a good wood preservative will result in a pole that will give good service. A butt-treated pine pole costs considerably less than an untreated cedar pole in this locality.

Lodgepole Pine. — Lodgepole pine is cut to a limited extent for poles. It grows at high altitudes in the Rocky Mountains. It decays quickly in contact with the soil, but is durable when not so exposed. The tree grows tall and straight, with very little taper and makes a well-shaped pole. In certain parts of the West, where there are large bodies of fire-killed lodgepole that remain standing for many years, sound and thoroughly seasoned, conditions for effective treatment are excellent. If given a butt treatment, this dead timber makes a durable pole, and in many localities the cost of the pine pole plus the cost of the treatment is less than that of the Idaho cedar untreated. The sapwood of pole-sized timber may be an inch or an inch and a quarter thick.

DEFECTS IN WOOD USED FOR POLES AND CROSS ARMS. — (*See also Timber.*) The following are the defects in timber which are frequently referred to in specifications for poles and cross arms.

Pith. — The pith of a tree is the central core about which the annual rings are formed. It goes through the tree from top to bottom and branches into the limbs. The pith is quite thick, usually 1/8 to 1/5 inch in Norway pine and in the southern species, though much less so in white pine and is very thin 1/15 to 1/25 inch in cypress, cedar and larch. The pith of the tree is the weakest part on account of the many knots which it invariably and necessarily contains.

Sapwood. — The sapwood of a tree is a zone of wood next to the bark, 1 to 3 or more inches wide and containing 30 to 50 or more annular rings (in coniferous trees). It is of lighter color than the inner, darker part of the log which is the heartwood. Sapwood changes to heartwood as the tree grows.

The width of the sapwood is small for longleaf and white pine and great for loblolly and Norway pines. In old trees of longleaf pine the sapwood forms about 40 per cent of the merchantable log, while in the loblolly and in all young (coniferous) trees the bulk of the wood is sapwood.

Sapwood, being the normal condition of the outer rings of a tree, is not a "defect" in poles, where the whole cross section of the tree (except bark) is used. Being weaker and more liable to decay it is considered a "defect" in pins and cross arms, which are better if made from the heartwood only.

Cup-Shakes. — These are cracks extending circumferentially at one or more places, caused by the separation of the annual rings.

Doatiness. — This is a speckled stain found in beech, American oak and other timber, due to incipient decay. It is produced by imperfect seasoning or by exposure for a long period to a stagnant atmosphere.

Heart-Shakes. — These are splits or clefts occurring in the center of the tree. They are common in nearly every variety of timber and are very serious when they twist in the length, as they interfere with the conversion of the tree into boards or scantlings. They sometimes divide the log in two for a few feet from the end.

Star-Shakes. — When several heart-shakes occur in one tree they are called star-shakes from the appearance produced by their radiation from the center.

Wind-Cracks. — Shakes or splits on the sides of a balk (a log which has been squared off) of timber, caused by shrinkage of the exterior surface, are called wind-cracks.

Dry Rot. — Dry rot is a special form of decay in timber caused by the growth of a fungus which spreads over the surface like a close network of threads, white, yellow or brown, and causes the inside to perish and crumble. Causes which render timber favorable to the growth of this fungus are; large proportion of sapwood; felled at wrong season when full of sap; if cut down in the spring or fall of the year instead of in midwinter or midsummer, when the sap is at rest; stacked for seasoning without sufficient air spaces being left; fixed before thoroughly seasoned; painted or varnished while containing moisture. (Six preceding definitions from *Carpentry and Joinery* by *Paul N. Hasluck.*)

Sound Knot. — A sound knot is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixed by growth or position that it will retain its place in the piece.

Loose Knot. — A loose knot is one not firmly held in place by growth or position.

Pith Knot. — A pith knot is a sound knot with a pith hole not more than one-fourth of an inch in diameter at the center.

Encased Knot. — An encased knot is one which is surrounded wholly or in part by bark or pitch. Where the encasement is less than one-eighth of an inch in width on both sides, not exceeding one-half the circumference of the knot, it shall be considered a sound knot.

Rotten Knot. — A rotten knot is one not as hard as the wood it is in.

Pin Knot.— A pin knot is a sound knot not over one-half inch in diameter.

Spike Knot.— A spike knot is one sawn in a lengthwise direction. The mean or average width shall be considered in measuring these knots.

Pitch Pocket. — A pitch pocket is an opening between the grain of the wood containing more or less pitch or bark.

Pitch Streak. — A pitch streak is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains — that is, the coarse-grained fiber, usually termed "spring wood" — is not saturated with pitch, it shall not be considered a defect.

Wane.—Wane is bark, or lack of wood from any cause, on edges of timber.

Shakes. — Shakes are splits in timber which usually cause a separation of the wood between annual rings.

Checks.— Checks are splits in timber, which usually cause a separation of the wood across annual rings. (Last twelve definitions are those used in the timber-test work of the Forest Service in describing defects. *Forest Service Circular 38, Revised.*)

Wind Shake. — A crack or incoherence in timber produced by violent winds while the timber was growing.

Wind. — A turn or bend. A piece of timber is out of wind when it is perfectly straight or flat.

Warped.— Twisted out of shape by seasoning.

Cat-Faces. — Old wounds, partially overgrown, leaving a long, narrow, dead surface exposed.

VOLUME AND WEIGHT OF POLES.— A quick way to find the approximate volume of a pole is to multiply the area of the circle at the center of gravity

by the length of the pole. The formula for the volume, considering a pole as a frustrum of a cone is

$$v = \frac{\pi}{1728}(d_1^2 + d_1d_2 + d_2^2)h,$$

where v = volume in cubic feet; d_1 = diameter at butt in inches; d_2 = diameter at top in inches; h = length of pole in feet.

The following table gives the volume of some standard poles:

Kind of pole	Nominal size		Volume, cubic feet
	Diameter, inches	Length, feet	
Chestnut	7	30	20.0
Southern white cedar	7	30	20.8
Northern white cedar	7	30	17.6
Western red cedar	8	40	27.3
Western yellow pine	8	40	26.0

The weight of a pole may be found by multiplying its volume in cubic feet by its weight per cubic foot. The following table gives the weight per cubic foot.

WEIGHT PER CUBIC FOOT OF POLES

Kind of pole	When cut		When seasoned	
	Weight,* pounds per cubic foot	Moisture, per cent of dry weight	Weight,* pounds per cubic foot	Moisture, per cent of dry weight
Southern white cedar	38.9	88	25.0	21
Chestnut (N. C.)	56.5	101	43.2	54
Chestnut (N. J.)	51.8	85	42.2	50
Chestnut (Pa.)	54.0	92	40.7	45
Chestnut (Md.)	56.4	86	44.9	48
Northern white cedar	34.2	90	22.9	27
Western red cedar	42.4	133	23.5	29
Western yellow pine	66.6	154	30.3	16

* Including contained moisture.

SEASONING.— Poles should be seasoned because it increases their resistance to decay, increases their strength and decreases their weight. The strength of partially seasoned timber, other things being equal, increases as the amount of moisture it contains decreases. Thoroughly seasoned timber of small sizes is sometimes three or even four times as strong as the same timber, when green.

Seasoning of poles reduces their weight, commonly from 16 to 30 per cent, and even more for some species, with a corresponding decrease in the cost of transportation. Thorough seasoning is essential if the poles are to be treated with preservatives. The percentage of moisture in a pole when cut varys with the season when cut as shown in the table at top of p. 1068.

In general, poles cut during the spring and summer lose weight most rapidly. Poles cut during autumn and winter lose weight less rapidly, but more regularly.

Too rapid seasoning may be detrimental to the timber by causing excessive checking. Shrinkage of poles during seasoning is very slight and does not exceed 1 per cent on the circumference.

MOISTURE CONTENT WHEN CUT, PER CENT OF DRY WEIGHT

Kind of pole	Spring	Summer	Autumn	Winter
Southern white cedar (N. C.)	68	77	87	88
Chestnut (N. C.)	97	91	95	101
Chestnut (N. J.)	81	83	81	85
Chestnut (Pa.)	89	92	88	88
Chestnut (Md.)	83	84	85	86
Northern white cedar (Mich.)	77	82	79	90
Western red cedar (Cal.)	...	133	...	...
Western yellow pine (Cal.)	149	147	145	154

The time in months required for poles cut at different periods of the year to season to approximately air-dry weight is as follows:

TIME REQUIRED FOR SEASONING

Kind of pole	Spring	Summer	Autumn	Winter	Moisture content* seasoned
	Months	Months	Months	Months	Per cent
Chestnut (Md.)	5	4	8	7	55
Southern white cedar (N. C.)	3	3	8	5	26
Northern white cedar (Mich.)	12	9	7	6	37
Western red cedar (Cal.)	....	....	....	....	43
Western yellow pine (Cal.)	5	3	9	6	25

* The average amount of moisture remaining in the poles after seasoning as above in per cent of the weight of the dry wood.

ROOFING. — If the top of a pole is lef flat rain water will not run off rapidly and will penetrate the pole by following the grain, causing early decay of the pole top. Poles are accordingly "roofed" by cutting the top to give an inclined surface which is sometimes conical but usually is merely two inclined planes meeting in a horizontal ridge. The angle of the planes with the horizontal is usually 45 degrees. Where a bracket is to be bolted to top of pole a flat strip from ½ to 1 inch in width is sometimes left, instead of a sharp ridge, in order to leave more material in the pole top where the strain from the upper bracket bolt comes. Roofs should be painted to close the grain which is porous, in order to prevent the entrance of water.

PRESERVATIVE TREATMENT. — The forest service estimate that it requires 190 years to grow a 30-foot cedar pole whose average life, when set in the ground in its natural state, does not exceed 15 years. They also estimated in 1907 that 800,000 miles of pole line were then in operation containing 32,000,000 poles and requiring 2,650,000 poles per annum for maintenance. They conclude

that the enormous demand must soon deplete the supply and have made extensive experiments on preservative treatment as a means of conserving the pole supply.

Preservative treatments are used to increase the resistance of poles to decay. The advantages of such treatment are:

1. It increases the life of the pole.
2. It makes possible the use of smaller poles as less allowance need be made for decay.
3. It makes possible the use of species of timber not naturally durable.

The butt of the pole near the ground line is most subject to decay and treatment of the butt alone is usually deemed sufficient. In some of the Southern states the whole pole is subject to decay, in which case the whole pole is treated.

Cause of the Decay of Timber. — Decay of wood is due to low forms of plant life called fungi. The germs of decay are not inherent in the wood. The wood-destroying fungi start from the outside, either from adjacent rotten wood or by spores, which correspond to seeds, being carried by the wind and deposited on the surface. While the fungi from these spores begin at the "outside" of the wood, this surface must be understood to include all holes or cracks which the spores may enter.

Fungi require for their growth and development air, heat, moisture and food. Warmth, preferably between 60° and 100° F., favors decay. Cold retards it and temperatures above 150° F. prevent it. Under water or deep under the surface of the ground where the air is excluded, decay does not take place. Ordinarily wood which is seasoned until it is air-dry does not contain sufficient moisture to support the growth of fungi.

Preservatives. — The best method of checking the growth of fungi is to deprive them of food. This can be done by injecting poisonous substances into the timber. These substances are called preservatives. Of the many antiseptics which have been proposed for the preservation of timber only four have been largely used with success in the United States. These are creosote, zinc chlorid, corrosive sublimate and copper sulphate. Copper sulphate has fallen into almost total disuse. At present creosote and zinc chloride, pure or in mixture, are the only preservatives which are in general use.

Corrosive Sublimate (Bichlorid of mercury). — This is used in the so-called "kyanizing" process. This process consists in steeping the timber in a dilute solution of corrosive sublimate long enough to insure thorough penetration.

Zinc Chloride. — Zinc chloride is an excellent antiseptic; it is obtained by dissolving metallic zinc in hydrochloric acid. This is further diluted by water before it is used for wood preservation. Zinc chloride is much cheaper than creosote, and since it is shipped in the form of a solid the freight charges are considerably less. Zinc chloride is soluble in water, being in fact, injected into the timber in water solution and so when timber treated with it is exposed to moisture the leaching out of the salt is only a question of time. Hence zinc chloride is most commonly used in comparatively dry situations.

Creosote. — Creosote is a by-product of coal tar, which is produced at most plants for the manufacture of illuminating gas and at by-product coke-oven plants. Wood tar, when distilled in a similar manner, gives "wood creosote," which like that derived from coal tar, possesses strong antiseptic properties. There is also on the market a so-called creosote, a by-product of water-gas tar or tar manufactured from kerosene oils, which, for wood preservation, is probably inferior to the true creosote. In general, however, by "creosote" is meant the dead oil of coal tar.

Creosote is not a single chemical compound but a mixture of a number of compounds. Not only does the relative proportion of the several constituents vary, but some may be absent or other compounds, not normally constituents of creosote, may be present. Creosote proper is the fraction of oil passing over between 240° C. and 270° C. during the first distillation of the crude coal tar. In practice, however, many of the creosote oils of commerce contain considerable amounts of materials having boiling points higher than 270° C. and lower than 240° C. Some commercial creosotes are rather thin oils, some are almost entirely solid with naphthalene and some are heavy oils with a large proportion of high-boiling constituents.

An analysis of creosote in well-preserved timbers (*Forest Service Circular 98*), led to the conclusions that light oils, boiling below 205° C., will not remain in timber, but that heavy oils, containing a high percentage of anthracene oil, will remain almost indefinitely and protect the wood from decay and boring animals.

The cost of creosote in carload lots (including transportation) is (1911) about 10 cents per gallon for points east of the Mississippi River and in the vicinity of the Gulf ports west of the Mississippi. West of the Rocky Mountains the cost is about 20 cents per gallon. A gallon of creosote is estimated to be 8½ pounds.

Patented Preservation. — There are many other patented substances known by various names, but most of them have for their base creosote or zinc chloride.

Carbolineum. — Carbolineum, like creosote, is derived from the distillation of coal tar. The compounds included in carbolineum are derived from the coal tar at a higher temperature of distillation and are therefore somewhat different.

Crude Petroleum. — Crude petroleum has been experimented with but there is little definite knowledge of its value as a wood preservative.

Methods of Treatment. — The methods of applying the preservatives to the pole are the brush treatment, open tank treatment and pressure tank treatment.

The brush treatment is applied to a part of the butt at the ground line, the open-tank treatment to the whole butt and the pressure-tank treatment to the whole pole.

The brush treatment is least expensive and gives the least protection and the pressure tank is most expensive and gives the most protection.

For a full description of these methods of treatment and estimates of cost see *U. S. Forest Service Circulars, Nos. 84, 147, etc.*

An estimate in 1911 for 30 ft. 7 in. poles for a two-coat brush treatment of the butts with creosote was from 15 to 20 cents per pole in the East and from 20 to 30 cents per pole in the West. An estimate for the open-tank treatment of the butt was 67 cents per pole with creosote and 65 cents per pole with zinc chloride.

LIFE OF POLES. — Statistics compiled by the National Electric Light Association give the following figures for the average life of *untreated* poles; the figures for *butt-treated* poles are according to estimates by the U. S. Forest Service.

Untreated	Years	Butt-treated	Years
Cedar	13.5	Chestnut	20
Chestnut	12.0	Western cedar	20
Cypress	9.0	Northern white cedar	22
Pine	6.5	Pine, in dry climates	20
Juniper	8.5		

Records of the German Postal and Telegraph Department covering 52 years give an average life of 20.6 years for creosoted pine poles.

SPECIFICATIONS FOR POLES. — In the report of the Committee on Overhead Line Construction of the National Electric Light Association (abbreviated N.E.L.A.) are given very complete specifications for chestnut, eastern white cedar and yellow pine poles. Space does not permit of the incorporation of these specifications here; copies may be had from the Secretary of the National Electric Light Association. The report is also given in the *Proc. N.E.L.A.* for 1911, Vol. II, p. 374.

FORCES ACTING ON A POLE. — A pole is subject to the following forces:

(1) Vertical forces due to weight of pole, wires, sleet, etc., and to downward pull of guys.
(2) Lateral horizontal forces due to wind across line on pole, wire, sleet, etc.
(3) Longitudinal horizontal forces due to unbalanced pull of wires.
(4) Torsional forces due to unbalanced pull of wires.

A pole is strong as regards the vertical forces but weak for horizontal forces and the cross arms are weak for the torsional forces. The theory of good line work is, therefore, first to reduce the horizontal and torsional forces as much as possible by balancing the stresses and second to convert remaining unbalanced horizontal stresses into vertical stresses on the pole by the use of guys.

In practice the lateral horizontal force of the wind is one which cannot ordinarily be provided for by guys. Calculations for strength of poles, when made, are ordinarily limited to the effect of side wind.

Breaking of Pole by Cross Wind. — The principal forces tending to break a pole are wind pressures on pole and conductors when the wind blows transversely. These tend to break it by cross bending.

Let M_1 = moment of the wind on the pole,
M_2 = moment of the wind on the wires,
M = moment of resistance of the pole.

Then the condition that the pole shall not break is that

$$M_1 + M_2 < M.$$

The calculation of M_1, M_2 and M is given below.

Moment of Wind on Pole (M_1). — Moment at ground level due to wind pressure on pole is

$$M_1 = \frac{P_1 H_1^2 (D_1 + 2 D_2)}{72},$$

M_1 = moment at the ground in pound-feet,
P_1 = wind pressure in pounds per sq. ft. of projected area of pole,
H_1 = height of pole in feet,
D_1 = diameter of pole at ground in inches,
D_2 = diameter of pole at top in inches.

The maximum bending moment due to horizontal forces at the top of the pole is ordinarily assumed to be at the ground level; it is really a little below ground level and opposite the center of pressure of the resistance furnished by the ground.

Moment of Wind on Wires (M_2). — Moment at ground level due to wind pressure on the wires is

$$M_2 = \frac{P_2 H_2 n d \ (S_1 + S_2)}{24},$$

M_2 = moment at the ground in lb.-ft.,
P_2 = wind pressure in pounds per sq. ft. of projected area of wires,
H_2 = height of wires above ground in feet,
n = number of wires,
d = diameter of wires (including ice) in inches,
S_1 and S_2 = lengths of adjacent spans in feet.

Where wires are of different diameters or at different levels the formula is to be applied to each size and each level separately and moments summed.

Moment of Resistance (M). — The moment of resistance or strength of a circular pole for cross bending is

$$M = \frac{f\pi D^3}{384} \quad \text{or} \quad = \frac{fD^3}{122}.$$

M = moment of resistance of the section considered in lb.-ft.,
f = fiber stress in pounds per sq. in.,
D = diameter of pole in inches.

The maximum allowable moment M is found by using the maximum allowable value for the fiber stress f.

Fiber Stress (f) **and Actual Tests of Strength.** — The following table gives the value of the fiber stress for various kinds of timber and the actual breaking load from tests of a number of poles.

FIBER STRESS AND BREAKING LOAD

(1) *Forest Service Cir., No. 213;* green, clear pieces.
(2) L. W. Winchester, *Elec. W., March 16, 1911;* top circumference 17 to 24.5 inches, poles set in ground from 4 to 6 ft., force applied 22 ft. to 26 ft. above ground.
(3) *Forest Service Cir., No. 204;* 7 in. top diameter, force applied at top.
(4) *Pac. Tel. & Tel. Co.;* from 6 to 9 in. top diameter, force applied at top.
* Modulus of Rupture.

Weakest Point of a Pole. — A pole is approximately a truncated cone in shape. For a bending force applied at one end such a cone is weakest at the point where the diameter is 3/2 the diameter at the point (near the small end) where the force is applied. A pole with 8-inch diameter at the cross arm is, therefore, weakest where it is 12 inches in diameter and may be expected to break at this point provided this point is above the place where maximum bending occurs. If it is less than 12 inches in diameter at the point of maximum bending then the break may be expected here. This rule must be considered approximate as it neglects the fact that the pole is not homogeneous, i.e., outer annual rings are sapwood and inner are heartwood, and also neglects effect of knots, etc.

ATTACHMENT OF CROSS ARMS TO POLES. — Wooden cross arms are attached to wooden poles:

(1) By gaining the pole, see below.
(2) By one or two lag screws or bolts.
(3) By one or two cross-arm braces.

The forces at the point of attachment which these fastenings must resist are:

(1) A force vertically downward, equal to weight of cross arm, pins, insulators and wire (including sleet).

(2) A horizontal force parallel to axis of arm, equal to pressure of wind blowing across line on wires.

(3) A horizontal force at right angles to axis of arm: (a) toward pole or (b) away from pole and equal to difference in pull of wires on two sides of arm.

(4) A couple in a vertical plane parallel to arm, equal to difference in moments of weight on the two ends of arm.

(5) A couple in a horizontal plane parallel to arm, equal to difference in moments of wire pull on the two ends of arm.

(6) A couple in a vertical plane at right angles to arm, equal to difference in moments of wire pull (caused by pin leverage) in the two directions.

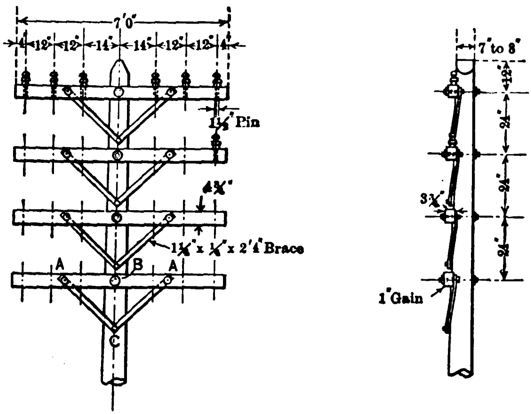

Fig. 1. Pole Top Framing, Single Arm

Framing and Hardware. — Typical framing and hardware for the three principal combinations of arms (single arms, double arms and buck arms on corner poles) are shown in Figs. 1, 2 and 3, respectively. These are standard framings of the Stone & Webster Engineering Corp. The arms used are shown in detail in Fig. 1 of the article on *Cross Arms*. The arms shown are all 6 pin,

but the framing would be the same, except for length of arm for 4-, 8- or 10-pin arms.

Gaining. — A gain is a notch cut in the side of a pole to receive a cross arm. The width (vertical dimension) of the gain should be just large enough for the cross arm. The depth of gain varies from ½ to 1 inch. With gains shallower than ½ inch the cross arm has insufficient support below and the flat bearing surface at the back is inadequate unless the pole is of larger diameter than usual. Deep gains greatly weaken the top of the pole especially when double arms are used. Gains should be painted before arms are attached to prevent moisture entering the wood through the cut surface.

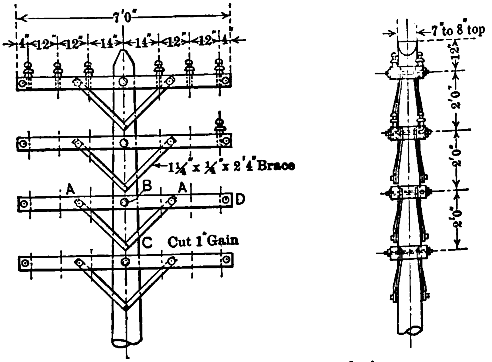

Fig. 2. Pole Top Framing, Double Arms

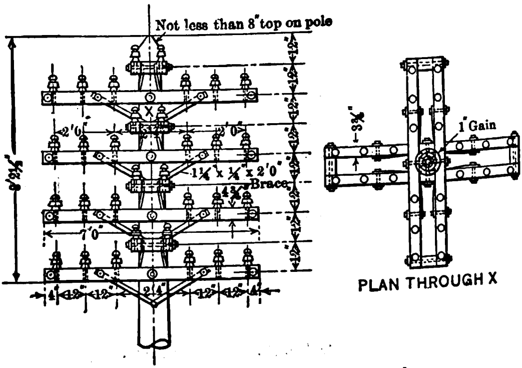

Fig. 3. Pole Top Framing, Corner Poles

Specification for Framing. — Gaining shall be as follows:
Top of pole to center of top gain, 12 inches.
Center to center of gains, 24 inches.

Gains for buck arms shall be located centrally between gains for main arms. Gains shall be cut not over 1 inch deep.

Arms shall be fastened to pole by one through bolt. Back of pole shall be flattened to give true bearing surface for washer under head of bolt. Each arm shall be braced by two braces fastened to back side of arm. Ends of double arms shall be separated by spacing blocks and shall be bolted together.

Specification for Hardware. — All hardware shall be galvanized iron.

Bolts. — Arms shall be fastened to pole with one ⅝-in. machine bolt. Double arms shall be fastened together by one ⅝-in. machine bolt at each end. Above bolts shall have 6-in. thread to allow for variation in thickness of poles. For fastening double arms to poles stud bolts having a nut at each end shall be used. Braces shall be fastened to arms by ⅜-in. machine bolts.

Washers. — Square-cut iron washers shall be used at both ends of bolts fastening arms to poles and at both ends of bolts fastening double arms together. Round-cut washers shall be used with machine bolts for fastening braces to arms.

Nuts. — Square nuts shall be used.

Braces. — Two braces shall be used on each arm. Braces shall be 28 in. by 1¼ in. by ¼ in. except on corner poles, where 24 in. by 1¼ in. by ¼ in. braces shall be used.

Lag Screws. — Braces shall be fastened to pole by ½ in. by 4 in. lag screws.

DEPTH OF SETTING IN GROUND. — The following table gives the depth of setting recommended by the National Electric Light Association.

Total length of pole, feet	Depth of setting, feet		Total length of pole, feet	Depth of setting, feet	
	Straight line	Curves and corners		Straight line	Curves and corners
30	5.0	6.0	60	7.0	7.5
35	5.5	6.0	65	7.5	8.0
40	6.0	6.5	70	7.5	8.0
45	6.5	7.0	75	8.0	8.5
50	6.5	7.0	80	8.0	8.5
55	7.0	7.5			

GUYING OF POLES. — A guy is ordinarily composed of guy wire, clamps, strain insulators, turnbuckles (sometimes) and guy stub or guy anchor.

Guy Wire. — Iron wires are used for guy wires but should always be galvanized (*see Galvanizing*). Solid wire was formerly common but stranded cable (called "strand") is now generally used. Various sizes have been used but the ⅜-inch is probably the best. The N.E.L.A. specification for the two sizes recognized by them is:

Size	Strands	Size of individual wires, B. W. G.	Ultimate breaking strength
Inch			Pounds
¼	7	14	2300
⅜	7	12	5000

Strain Insulators. — Strain insulators are placed in guys to prevent the lower part of the guy wire, which is accessible to the public, becoming charged through leakage or contact with a conductor. Two strain insulators should be used, one located about 5 feet from the pole and the other 8 feet above the ground.

Two types of strain insulator are used. In one the insulation (usually impregnated wood) is in tension, while in the other (usually porcelain) it is in compression. The former has the disadvantage that failure of the insulation causes mechanical failure of the guy. The latter has the disadvantage that the insulator may fail and the guy become charged without the failure being readily apparent. The N.E.L.A. specification favors the latter type and requires a mechanical strength of twice the strength of the guy wire and a wet flash over electrical test of four times the line voltage.

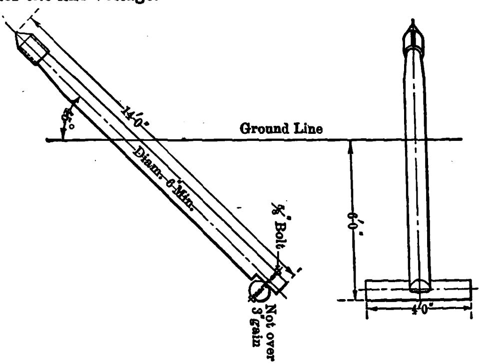

Fig. 4.

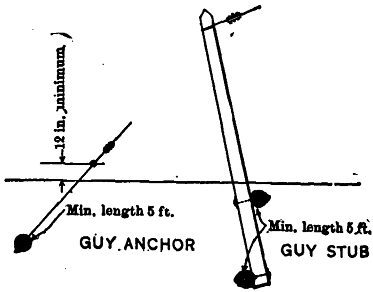

Fig. 5.

Guy Stubs and Guy Anchors. — A common guy stub is shown in Fig. 4. This is made from parts of defective poles and is fastened together with a cross-arm bolt. Fig. 5 shows another common form of guy stub and a common guy anchor.

There are also various forms of patented anchors which screw into the earth or are placed or driven into small holes and then expanded. These are designed to economize labor of installation of standard anchors.

REPAIRING DECAYED POLES. — Where poles have been weakened at the ground line by decay the strength may be restored by cutting off the decayed butt and resetting pole, thus reducing its height by six to eight feet. When reduction of height is not permissible, the pole may be stubbed by setting along side of it a short pole or stub extending a few feet above ground to which the old pole or the undecayed part above ground is bolted or otherwise fastened. This method does not look well and is unsuitable for city distribution lines but has been used for transmission lines. A more recent method is to reinforce the decayed pole by a sleeve of concrete (usually reinforced) extending above and below the decayed portion. (*See Electrical World, April 1, 1909 and Aug. 25, 1913 for Orr patented process.*)

COST OF POLES. — The cost of wooden poles varies between wide limits, depending upon the part of the country in which they are purchased. The following figures are rough approximations and are exclusive of freight.

APPROXIMATE COST OF POLES

Length, feet	Chestnut, Pennsylvania	Cedar, Iowa	Cedar, Minnesota
25	.....	$2.30*	.....
30	$3.00*	3.80*	.....
35	3.50*	6.10*	.....
40	4.25†	7.50*	$8.00†
45	6.00†	9.75*	11.75†
50	8.50†	11.20*	14.50†
55	10.00†	13.80*	.....
60	14.50†	16.70*	.....

[R. A. PHILIP and CABOT STEVENS.]

POTENTIOMETERS. — (*See also Cells, Standard; Galvanometers; Resistors, Standard.*) A potentiometer is primarily an arrangement of resistances for the accurate comparison of two potential differences by balancing one against the other. In connection with suitable resistance standards (*see Resistors, Standard*) it may also be used for the accurate measurement of electric currents. The accessories for making ordinary d-c. measurements are a standard cell (*see Cells, Standard*) and a galvanometer (q.v.), and suitable keys or switches. For making a-c. measurements certain additional apparatus is required; see below under *Alternating Current Potentiometer*.

USES OF THE POTENTIOMETER. — For the calibration of current, voltage and power-measuring instruments, both d-c. and a-c., the potentiometer is the most accurate and satisfactory instrument available. A technical laboratory relies almost entirely upon the standard Weston (or Clark) cell and a set of standard resistances as its ultimate or primary standards, leaving the testing of the accuracy of these latter to a central standardizing bureau, such as the Bureau of Standards at Washington. It is, of course, convenient to have suitable "precision" ammeters, voltmeters and wattmeters as secondary laboratory standards but, as such secondary standards tend to "lose their calibration," they should be frequently checked against the standard cell and standard resistances by means of a potentiometer.

PRINCIPLE OF THE POTENTIOMETER (Figs. 1 to 3). — The potentiometer in its simplest form consists of a uniform wire stretched over a scale divided into a number of even parts, say 1500. A battery B (Fig. 1) having an e.m.f. of about 2 volts and rheostat R are connected in series with this wire and two contact points A and S are provided, one contact S being movable. G is a galvanometer. At P there may be connected at will a standard cell or any other source of potential difference.

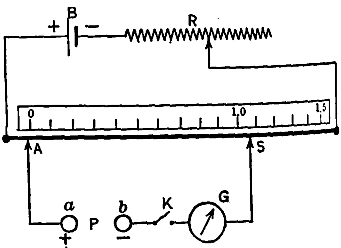

Fig. 1. Simple Potentiometer

At P is first connected a standard cell, say a Weston cell, having an e.m.f. of 1.01830 volts and the contact A is placed at 0 and the contact S at 1.0183 on the scale. By varying the rheostat R it is possible to so adjust the current in the slide wire that the fall of potential between A and S due to the current from the battery B is exactly 1.0183 volts. This can be determined by closing the switch K; if R is properly adjusted there will be no deflection of the galvanometer. Care must be taken that the positive terminals of both B and the standard battery are connected to the same end of the wire.

To measure any other p.d. the standard cell is taken out of circuit and the terminals between which the p.d. is to be measured are connected to a and b respectively. The contact S is then moved until the galvanometer shows a balance. The corresponding position of the contact S, as read on the wire, then gives the value of this p.d. in volts.

Increase of Range by Use of Volt Box or Multiplier. — To measure voltages above 1.5 one must resort to the "volt box" or "multiplier," which is simply a standard high resistance, R_1 (Fig. 2) being provided with taps, so arranged that a definite fraction of the total drop can be measured on the poten-

tiometer. The unknown p.d. is connected at E, Fig. 2, the terminals a and b being the same as the like-lettered terminals in Fig. 1. The potentiometer reading would then be multiplied by 10 or 100 depending on the position of the switch D. The resistance R_1 must be sufficiently large so that the current taken by R_1 does not appreciably affect the value of the p.d. in the circuit being tested.

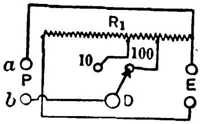

Fig. 2. Volt Box

Increase of Accuracy by Use of Additional Series Resistance. — The accuracy of measurement may be increased by inserting in series with the slide wire a known multiple of the resistance of, say, 1000 divisions of the slide wire. This is equivalent to increasing the length of the slide wire, and therefore, each division on the scale represents a correspondingly smaller fraction of a volt.

Current Measurement. — If it is desired to measure current, the drop across a known low resistance r is measured as shown in Fig. 3. The resistance r is usually so adjusted that its resistance between the potential terminals PP' is an even fraction of an ohm, in which case the potentiometer reads the current directly, with the exception of the proper pointing of the decimal. For instance, using a 0.01 ohm standard the potentiometer reading is to be multiplied by 100.

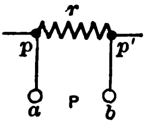

Fig. 3.

Caution. — In using any form of potentiometer a balance with the standard cell in circuit should always be obtained just before and after a balance with the unknown p.d. in circuit. In other words, the potentiometer current should always be checked both before and after a measurement.

TYPICAL DIRECT-CURRENT POTENTIOMETERS. — Potentiometers are made in such varied forms that it would take considerably more space than is available to describe them all. The most generally used direct-current types are the high-resistance "null" type, the low-resistance "null" type and the Brooks deflection type.

The Brooks potentiometer is particularly well adapted to the requirements of a large electrical engineering laboratory, where many instruments must be checked and kept in adjustment, and where it is imperative that the work be done with great speed, combined with a degree of precision ample for engineering work.

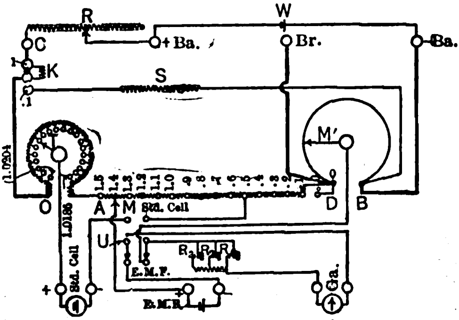

Fig. 4. Leeds & Northrup Potentiometer

Low-resistance Null Type (Fig. 4). — A diagram of the connections of a Leeds and Northrup low-resistance null-type potentiometer is shown in Fig. 4.

Fifteen 5-ohm coils are connected to the studs of a dial switch, the contact M arranged to make contact with any stud. The slide wire DB consists of 11 turns of manganin wire wound on a marble cylinder 6 inches in diameter. The contact M' is mounted on the inside of a light aluminum hood, which serves to protect the slide wire from dust. It moves over the entire length of the slide

wire and carries a scale from which the number of turns and the fraction of a turn can be easily read.

This potentiometer is designed for use with commercial "standard" Weston cells, which differ slightly in e.m.f. Each one, however, is accompanied by a certificate giving its e.m.f.

The switch T should be set at the stud corresponding to this stated e.m.f. In other words, the switch T is used for adjusting the potentiometer to the particular cell which is used. The rheostat R is then adjusted until no current flows through the galvanometer with the double-throw switch U thrown across the contacts marked Std. Cell.

In closing the galvanometer circuit close the keys R_3, R_2, and R_0 in the order stated. R_3 puts the galvanometer in series with a high resistance, R_2 puts the galvanometer in series with a medium resistance and R_0 puts the galvanometer in circuit without series resistance. If the potentiometer is considerably off balance this may thus be detected without causing a violent deflection of the galvanometer, and a closer balance obtained before the other keys are closed.

Range of Low-resistance Null Type. — With the rheostat R adjusted to give a perfect balance the current through the potentiometer is 1/10 ampere, and the drop across each coil and across 1000 divisions of the slide wire is consequently 0.1 volt and across 1 division of the slide wire 0.0001 volt.

Range-lowering Device. — The shunt S serves as a range-shifting device, by which the range may be reduced to 0.1 the normal, one division of the slide wire in this case being equal to 0.00001 volt. This shunt has such a resistance that when the plug opposite K is shifted to the lower hole the drop over AD will be 1/10 its previous value.

High-resistance Null Type (Fig. 5). — A diagram of the connections of a Wolff high-resistance null-type potentiometer is shown in Fig. 5. In this instrument the slide wire is dispensed with altogether. The double-dial switches are so arranged that the total resistance between the terminals B is constant and equal to 15,000 ohms irrespective of the position of the switches. The means whereby this is accomplished is evident upon tracing out the circuits in the diagram. By using this high resistance and keeping it constant, the effect of the contact resistances in the various switches is rendered negligible. The adjustments are made in the same manner as for the simple slide-wire potentiometer, except that instead of moving a sliding contact along a wire, one manipulates the various dial switches. The potentiometer circuit proper and all necessary keys and switches, are provided in this instrument. The accessories necessary for making measurements up to 15 volts are a regulating rheostat of about 5000 ohms total resistance, a standard cell, a suitable galvanometer and two cells of storage batteries or other source of e.m.f. of about 4 volts.

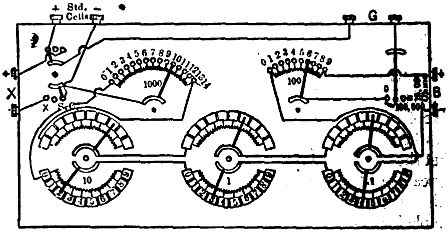

Fig. 5. Wolff's Potentiometer

Range of High-resistance Null Type. — This potentiometer has a range up to 15 volts in steps of 0.0001 volt and up to 1.5 volts in steps of 0.00001 volt.

Brooks Potentiometer (Fig. 6). — In this instrument no attempt is made to obtain an exact balance; the dial switches are set so near to the null point that

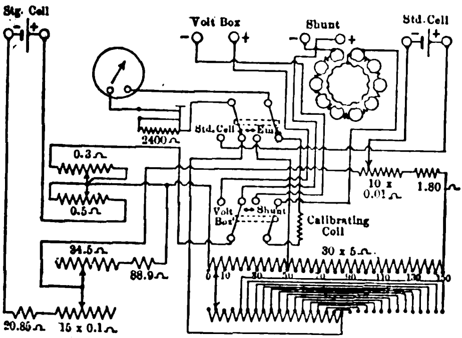

Fig. 6. Connections of Brooks Potentiometer

the galvanometer deflection is small. The galvanometer is so graduated that it gives the amount that must be added to the reading of the slides in order to give the unknown p.d. The potentiometer proper, regulating rheostat, galvanometer and necessary keys and switches are mounted in one box, making the instrument semiportable. The only accessories required to make measurements within the range of the instruments are a standard cell and storage battery.

Range of Brooks Potentiometers. — The instrument is made in two types, one model 3 for general laboratory work and the other model 5 for photometric work. The model 3 potentiometer has a range of from 0 to 1.5 volts (which may of course be extended by the use of a volt box), one step on the hand-operated dial corresponding to 0.05 volt and one division of the galvanometer scale corresponding to 0.001 volt. The model 5 potentiometer is similar to the model 3 but has a range of from 0 to 6 volts, one step on the hand-operated dial corresponding to 0.2 volt and one division of the galvanometer scale corresponding to 0.004 volt. Volt boxes having ranges up to 750 volts are made for use with either of these potentiometers.

The model 3 potentiometer may be used for current measurements up to 400 amperes with shunts that are not necessarily bulky or expensive. The model 5 instrument is not suitable for heavy-current measurements as the shunts require a large drop and are bulky and expensive.

For complete description of these instruments see *Bulletin of the Bureau of Standards, Vol. 8, No. 2.*

ALTERNATING-CURRENT POTENTIOMETER. — The principles involved in the use of the potentiometer for alternating-current measurements are the following: Referring to Fig. 1, a balance is obtained with a battery at B, a standard cell at P and the contact S at the point on the scale corresponding to the e.m.f. of the standard cell, and the current flowing in the potentiometer circuit noted by means of an electrodynamometer or a.c.-d.c. ammeter connected between B and A. The battery B is then replaced by a source of alternating current and the rheostat R adjusted until an alternating current of the same

effective value, as read on the electrodynamometer or ammeter, flows through the potentiometer. The standard cell at P is replaced by the unknown alternating p.d. to be measured and the galvanometer by an alternating-current galvanometer (*see Galvanometers*). To obtain a balance, however, it is now not only necessary that the contact S be moved along until the drop between A and S has the same effective value as the unknown p.d., *but also that this drop and the unknown p.d. have the same frequency and are in the same phase.* Consequently the p.d. at B must be supplied from the same source as the p.d. to be measured, and means must be provided for shifting the phase of one with respect to the other.

The coils of an a-c. potentiometer are wound non-inductively, and consequently the p.d. due to the potentiometer current is in phase with this current. Hence the phase adjustment consists in bringing the potentiometer current into phase with the unknown p.d.

Phase-shifting Device. — One means of shifting the phase of the potentiometer current with respect to the unknown p.d. is to use two small alternators mounted on the same shaft, with the field frame of one adjustable with respect to the other. This, however, can be more conveniently accomplished by using a device similar in construction to a polyphase-induction motor, the primary of which is supplied either from a two- or three-phase circuit, or from a two-phase circuit derived from a single-phase circuit by connecting a resistance and condenser in series, and tapping off the p.d. across the resistance for one phase and the p.d. across the condenser for the other phase. By setting the secondary of this phase shifter at a fixed angle with respect to the primary, a p.d. can be obtained from the secondary at any desired phase with respect to the source of supply. A phase-shifting device based on this principle, and so designed that the change of phase resulting from shifting the position of the secondary does not alter the effective value of the secondary e.m.f., has been recently devised by C. V. Drysdale (*Phil. Mag., 1909, Vol. 17, p. 402*). With this instrument the phase of the potentiometer current and p.d. to be measured may be adjusted to 0.1°.

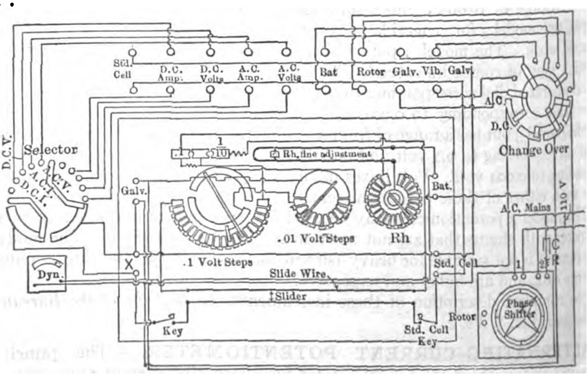

Fig. 7. Drysdale-Tinsley Alternating-current Potentiometer

Drysdale-Tinsley Alternating-current Potentiometer (Fig. 7). — A diagram of connections is shown in the figure. A vibration galvanometer is used as an a-c. detector and is tuned to the impressed frequency. The potentiometer is first balanced with an ordinary battery and standard cell and the reading of the electrodynamometer noted. By means of the change-over switch, alternat-

ing is substituted for direct current and the reading brought to the same point and held there. The phase of the potentiometer current is then roughly adjusted and the unknown p.d. is balanced as nearly as possible by shifting the potentiometer slides. The balance is then improved by shifting the phase of the potentiometer current and by resetting the slides; thus, by a process of double adjustment, the vibration galvanometer is brought to rest.

As the vibration galvanometer is a tuned instrument, *the frequency of the a-c. supply must be kept constant.* Also, the wave shape of the potentiometer current and that of the unknown p.d. must be the same, as the vibration galvanometer shows a *balance for the fundamental frequency only.*

Current and Power-Factor Measurements. — By the use of suitable non-inductive shunts alternating currents may also be measured with this potentiometer. Also, by noting the reading of the phase-shifting device corresponding to a balance first of the given p.d. and then for the given current, the phase angle between the p.d. and current can be obtained by taking the difference of the two readings.

Range of Drysdale-Tinsley Potentiometer. — This potentiometer has a range of from 0 to 1.5 volts in steps of 0.001 volt. With suitable non-inductive volt boxes its range may be extended to 750 volts. It may also be used, in conjunction with suitable shunts, for measuring alternating currents of any value.

PRECISION OF POTENTIOMETER MEASUREMENTS. — The precision obtainable with a potentiometer depends upon the accuracy to which the e.m.f. of the standard cell is known, the accuracy to which the various resistance coils in the potentiometer circuit and shunts are adjusted, and the relative magnitude of the various contact resistances, and the proportion of the total resistance in the potentiometer circuit. For a-c. measurements the accuracy is also dependent upon the inductance and capacity of the coils. The Bureau of Standards calibrate the Weston cell to 1/50 per cent. The various coils of a potentiometer are adjusted to different degrees of accuracy, little attention being paid to the absolute accuracy of coils as long as they bear definite relations to each other.* Instruments are calibrated as potentiometers to give the following accuracies.

PRECISION OF POTENTIOMETER MEASUREMENTS

Kind of potentiometer	Degree of precision, per cent	
	Voltage measurements	Current measurements
Low-resistance null type	1/50	1/20
High-resistance null type	1/50	1/20
Brooks	1/25	1/10

COST OF POTENTIOMETERS. — The following are approximate costs of the potentiometers proper, exclusive of the standard cell, galvanometer, volt box and shunts for current measurements:

Low-resistance null type	$240
High-resistance null type, rheostat not included	250
Brooks deflection type, including galvanometers	350

BIBLIOGRAPHY. — A complete bibliography on potentiometers is given in *Circular No. 21, Bur. Stand.*, 1910; H. B. Brooks, *Bull. Bur. Stand.*, Vol. 8, 1911, p. 395.

[H. PENDER AND H. R. RANKEN.]

POWER-FACTOR INDICATORS AND REACTIVE VOLT-AMPERE INDICATORS. — (*See also Alternating Currents; Generators, Alternating-Current; Wattmeters.*) A power-factor indicator is an instrument designed to give a direct reading, at any instant, of the power factor in a circuit or system of circuits as well as to indicate whether the current is leading or lagging; see *Alternating Currents*. The power factor of a single-phase circuit may be calculated from the readings of an ammeter, voltmeter and wattmeter. The power factor of a balanced three-phase circuit can also be calculated directly from the readings of the two wattmeters used to measure the power (*see Wattmeters*). A direct-reading power-factor indicator, however, is usually to be preferred for station purposes, since it gives the power factor directly and also indicates directly whether the current is leading or lagging.

Under certain conditions it is more convenient to obtain a direct measure of the reactive (wattless) power supplied to a circuit; ordinary wattmeters may be thus used as explained below.

MOVING-COIL TYPE. — Power-factor indicators of this type operate on the same principle as wattmeters of the electrodynamometer type, except that the coils are so arranged and so connected to the circuit that a differential action is produced which depends only on the power factor of the load.

Three-phase, Moving-coil Type. — Fig. 1 is a diagram of the three-phase power-factor indicator built by the G. E. Co. C and C' are current coils in series with one leg of circuit and P_1 and P_2 are potential coils connected as shown through the non-inductive resistances r_1 and r_2. Connections into and out of the moving coils are made by light spirals having very small torque, or through the bearings, so that the final position of the moving system depends solely upon the relative forces between the fixed and moving coils.

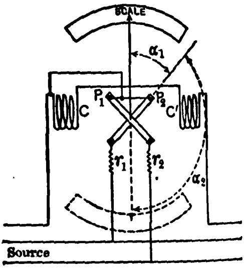

Fig. 1. G. E. Moving-coil Type

If the instrument is connected properly, the current coil acts with the two potential coils like the two elements of polyphase wattmeter (*see Wattmeters*). The torques of the two moving elements are developed in opposite directions. The torque of each element depends on the position of its potential coil. The potential coils are fixed with relation to one another at such an angle that the torque of one element always increases when that of the other decreases, due to the movement. Hence the needle will come to rest where the two torques are equal, and will give a scale reading dependent upon the ratio of the watts supplied to the two elements, i.e., in the case of a balanced load dependent on the ratio $\cos(30 - \theta) \div \cos(30 + \theta)$, where θ is the power-factor angle. Hence, for unity power factor, $(\theta = 0)$, the moving element will take up a position which is symmetrical with respect to the two potential coils, i.e., the pointer will take up a vertical position. For 50 per cent power factor, lagging, $(\theta = 60°)$, the moving element will swing to the right until the axis of the potential coil P_1 coincides with the axis of the current coil. Similarly, for 50 per cent power factor, leading, $(\theta = -60°)$, the moving element will swing to the left until the axis of P_2 coincides with the axis of the current coil. The character and range of the scale can be modified by varying the angle between the two potential coils.

Should the direction of flow of power reverse, the pointer would tend to take up the dotted position in Fig. 1. Some instruments are provided with scales to take advantage of this effect.

Another form of instrument of this type designed for unbalanced systems has three fixed coils, 120° apart, one for each phase. The movable element has three Y-connected non-inductive coils.

Two-phase Moving-coil Type. — Instruments for use on two-phase circuits are similar to the three-phase instrument, shown in Fig. 1, except that for the same scale the relative position of the two coils is different.

Single-phase Moving-coil Type. — Power-factor indicators are used only to a limited extent on single-phase circuits, this being in part due to the difficulty in designing an instrument of this type which will not be affected appreciably by even small changes in frequency. There is also but a limited demand for such instruments.

In construction and principle of operation the single-phase power-factor indicator is similar to the three-phase indicator described above. One of the movable coils is connected in series with a non-inductive resistance, and the other in series with an inductance, and both circuits are connected across the two mains; in this way the necessary phase relations are established in the two potential circuits. Since the current in the inductive circuit varies with the frequency, it is evident that the readings of such an instrument will be influenced by changes of frequency and of wave form. To overcome this difficulty various more or less successful modifications have been made in the simple arrangement described.

MOVING-VANE TYPE.—In place of the movable coils this type of power-factor meter contains a movable soft iron vane, which, in the case of polyphase instruments, is magnetized through a stationary coil carrying a current in phase with the voltage of one phase of the circuit. There is one stationary series coil for each phase, the arrangement being such as to produce a rotating field. The iron vane then takes up a position in which the direction of the flux produced in it by the potential coil when at a maximum is coincident with the direction of resultant flux due to the current coils. In the three-phase instrument three current coils, placed 120° apart, are used; in the two-phase meter two current coils at 90° are used. In the single-phase type the iron vane is magnetized by a stationary coil placed in series with the line, while the rotating field is produced by two potential coils 90° apart, one of which is connected to the line through an inductance, the other being connected to the same line through a non-inductive resistance. For the purpose of damping the deflections, an aluminum disk moving in the field of two permanent magnets is attached to the movable system.

REACTIVE (WATTLESS) VOLT-AMPERE INDICATORS.—Operating conditions on polyphase circuits are sometimes such that the reactive component of the volt-amperes in the circuit does not vary through wide limits of load between light load and full load, whereas the power factor may vary greatly. Under such circumstances it is frequently more convenient to have a direct measure of the reactive volt-amperes rather than the power factor; as, for example, in a railway substation employing synchronous converters (*see Converters, Synchronous*). This may be secured, as noted above, by using wattmeters suitably connected to the circuit. On a balanced three-phase circuit either a single-phase wattmeter, connected as shown in Fig. 2, or a two-element polyphase meter, connected as shown in Fig. 3, may be used; the instrument transformers are omitted when the voltage and current do not exceed the range of the wattmeter. The only difference between the connections shown in Fig. 3 and those for the two-element polyphase wattmeter for measuring power (Fig. 5 in article on *Wattmeters*) is that the two potential circuits are interchanged.

A wattmeter connected as in Fig. 2, reads $EI \sin \theta$, where E is the voltage between wires, I the line current, and θ the power-factor angle; to obtain the total reactive volt-amperes of the load this reading must be multiplied by $\sqrt{3}$. A two-element wattmeter connected as in Fig. 3 reads $2EI \sin \theta$, and to obtain the total reactive volt-amperes of the load this reading must be multiplied by $\sqrt{3}/2$; see article on *Wattmeters*. The instrument in either case may be calibrated to read the volt-amperes directly.

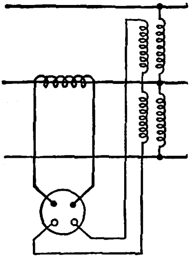

Fig. 2. Connections for Single-phase Reactive Volt-ampere Meter

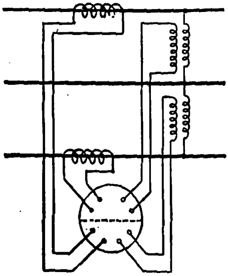

Fig. 3. Connections for Polyphase Reactive Volt-ampere Meter

RANGES OF THE VARIOUS TYPES. — The largest capacity of instrument of the moving-coil type for direct connection to the circuit is 100 amperes and 300 volts for the single-phase and 200 amperes and 600 volts for the two-phase and three-phase types. The range of power factor on standard instruments is from 0.60 leading to 0.60 lagging, although instruments with ranges as low as 0.00 leading to 0.00 lagging have been made.

Instruments of the moving-vane type have a current capacity of 5 amperes. They are made for direct connection to circuits of 110, 220 and 440 volts. For all other capacities and voltages the 5-ampere, 110-volt instrument with suitable current and potential transformers is used. The instruments are made for frequencies of either 25 or 60 cycles per second. The range of power factor on the moving-vane type of meter is unlimited.

Power-factor indicators of either type may be connected to instrument transformers which are used in connection with other meters.

Five amperes and 115 volts are standard for wattmeters used as reactive volt-ampere indicators, with transformers for higher ranges. However, single-phase instruments for direct connection, are furnished up to 200 amperes and 600 volts, and polyphase instruments for direct connection, up to 60 amperes and 600 volts.

COSTS. — The approximate prices of polyphase power-factor indicators of the moving-coil type, for current capacities of from 5 to 100 amperes and for voltages from 100 to 600 volts, range from $45 to $75. The price of the corresponding single-phase instruments, including the phase-splitting reactor, is approximately $10 more. Power-factor indicators of the moving-vane type for voltages from 110 to 440 cost approximately from $30 to $40, exclusive of current or potential transformers.

Single-phase wattmeters calibrated to read reactive volt-amperes cost about $45 each and polyphase wattmeters thus calibrated cost about $65.

BIBLIOGRAPHY. — See *Bibliography* in article on *Synchronizers*.

[L. T. Robinson and O. R. Schurig.]

POWER STATIONS, GAS-ELECTRIC. — (*See also Gas; Gas Engines; Gas Producers; Generators; Power Stations, Steam-Electric; Power Stations, Hydroelectric.*)

Number and Capacity of Units. — As gas engines have little overload capacity a total rating of engines should be installed sufficient to carry the extreme peak load and afford ample emergency reserve. In many cases the kilowatt rating of generators is made but 60 to 65 per cent of the horse-power rating of the engines, in order to provide overload generating capacity. This is not always wise, as the most efficient load of a gas engine is quite near its maximum capacity. The units in very large plants are usually of the horizontal, twin, tandem type and range from 4000 to 6000 h.p. in rating, the latter size being the largest available. Producers are quite flexible in capacity, but heavy forcing is apt to produce clinker and impair the quality of the gas. The total producer capacity usually corresponds with the total engine capacity, unless the load fluctuates greatly and considerable tank capacity for gas storage is available. In most cases not less than three engine and producer units should be provided.

Buildings. — The practice in this field follows quite closely that described in the article on *Power Plants, Steam-Electric* (q.v.). In a few cases producers are set in the open air. Producers and engines are sometimes in separate buildings. In the usual design the engine and producer rooms are parallel and electrical control galleries are provided on the side of the engine room opposite the producer room. The engine room should be spanned by an electrically operated crane with capacity sufficient to handle the heaviest engine part. In some important plants the producer room is also provided with a crane.

Producer Room Lay-out. — The gas producers are usually set in a single row extending the length of the producer room. Each unit comprises one or two gas generators, an evaporator, a scrubbing tower, a gas pump and tar filters grouped so that the path of the gas is toward the engine room. A coal bunker is often provided above the producers, preferably along the outside wall. Down-spouts to the charging bells of the several producers should be somewhat inclined and should have cut-off valves. When desired, automatic weighing hoppers may be attached between the bunker and each down-spout to record the coal consumption of each producer. In some producer rooms a shallow pit is provided along the front of the gas generators so that ashes may be raked into this pit. In other cases ashes are raked out onto the main floor to be carted away. A skeleton gallery of steel connecting the producers at their charging levels is often a convenience.

Engine Room Lay-out. — Horizontal engines are usually set in a single row with piston rods across the engine room. The power end of each unit is on the side of the gas supply and the electrical end on the side nearer the control gallery. In a-c. plants a group of independently driven exciters is placed near the middle of the room. The spaces between units and the clearances at their ends are determined by the room needed for erection, dismantling, making repairs and access during operation.

Piping. — The piping scheme is usually a simple parallel plan. A main gas header is provided and runs the length of the wall between the engine and producer rooms. Branches from this header run to each producer unit to each engine and to the storage tank. Piping may be of relatively light weight and needs no special provision for expansion, but all joints should be secure, as producer gas is of a poisonous nature. The storage tank may properly be at one end of the building. Each producer is usually set beneath a vent pipe or short steel chimney run a few feet above the roof to discharge the smoke and raw gases produced when starting up.

Space Required. — The following table shows the floor space provided per kw. of plant capacity in modern stations.

Plant capacity, kilowatts	Number of engine units	Number of producer units	Square feet per kilowatt	
			Engine room	Producer room
360	3	2	6.0	2.2
700	2	2	4.5	2.9
1,620	3	2	5.5	1.56
3,000	3	2	3.7	0.93
34,000 (a)	17	0	3.0	....

(a) Blast-furnace gas plant.

COST OF GAS POWER PLANTS. — The cost per kilowatt of gas power plants varies with the capacity of the plant, the number of units installed and the source of gas supply. The construction cost of engine plants using natural gas ranges from $65.00 to $100.00 per kw., depending on the size of plant. The construction cost of blast-furnace gas plants, including the necessary gas-cleaning equipment, ranges from $85.00 to $120.00 per kw., and of producer plants from $90.00 to $125.00 per kw. according to capacity. The cost per kw. diminishes very slowly above a plant capacity of 12,000 kw. The division of the construction cost per kw. in a 16,000-kw. producer-gas plant having eight engine units is approximately as follows:

Building and foundations	$ 15.00
Producers	19.50
Engines	40.00
Generators	10.00
Piping and auxiliaries	3.00
Wiring and switchgear	2.50
Service equipment	2.50
Engineering and contingencies	7.50
Total	$100.00 per kw.

Fuel. — Assuming the coal to have 12,000 B.t.u. per lb., about 1⅛ lb. coal are required per kw-hr. generated at full load; 1⅓ lb. per kw-hr. at ¾ load; and 1⅝ lb. per kw-hr. at ½ load. For coal of any other heating value the weight required is approximately inversely proportional to the B.t.u. per lb.

Water. — About 9 gallons of water per kw-hr. are required when the supply water is at 50° F., and about 13 gallons per kw-hr. when at 70° F.

Oil and Supplies. — Cost ranges from 0.06 cent to 0.1 cent per kw-hr.

Labor for Operation. — 1 fireman required for each producer in operation and 1 oiler for each engine in operation. Supervision, switchboard attendance, coal handling, etc., as for a steam-electric station. The total cost of labor for operation is usually about 50 per cent of the fuel cost.

Maintenance. — Total maintenance cost per annum ranges from 1.75 per cent to 2.25 per cent of the first cost of plant, depending upon the load factor since larger plants involve only an increased number of similar units and a proportionately larger building.

Fixed Charges. — These range from 10 per cent to 12 per cent of the first cost of the plant.

[W. E. Wickenden.]

POWER STATIONS, HYDROELECTRIC. — (*See also Power Stations, Gas-Electric; Power Stations, Steam-Electric; Dams; Generators; Hydraulics, Principles of; Hydrology; Pipes and Piping; Switchgear Equipment for Power Stations; Transformers; Water Wheels; etc.*) This article deals primarily with those features in which a hydroelectric plant differs from a steam electric plant; these features arise chiefly from the nature of the prime movers and from the use of the very high voltages (up to 150,000) at which power from hydroelectric stations is transmitted. The individual constituent items, such as generators, water wheels, transformers, switchgear, etc., are treated in the separate articles, dealing with these subjects. The following is a brief table of contents of this article:

LOCATION OF POWER HOUSE. — The location of the power station of a hydroelectric plant is determined primarily by the head utilized and by the location of the dam (*see Dams*). In the case of low head developments the substructure of the power station is usually a portion of the dam itself or a "wing" offset from it. In choosing the location of both the dam and the position of the power station relative thereto, particular attention should be paid to the liability of ice and débris clogging the intakes. For high head developments, using penstocks, the power station is so located as to give the maximum head consistent with economy of construction and availability of a suitable natural channel for carrying off the discharge. Available sites for storage reservoirs should also be considered.

The location of the development generally has to be such that high-tension transmission is necessary, so that provision must also be made for housing the transforming and high-tension switching apparatus.

DESIGN OF BUILDING. — (*See also Water Wheels and Their Setting.*) The design of power houses differs greatly, depending on the conditions which are to be met. It is affected to a very great extent by natural conditions, such as the location with respect to the stream, the condition of the soil, etc. Low and high head developments require different types of turbines and these may furthermore be of horizontal or vertical construction, necessitating entirely different lay-outs.

A hydroelectric power-house building is generally divided into two longitudinal bays, a front or main bay, containing the turbines and generators, and a rear bay containing the transformers, switching apparatus, etc.; see Figs. 1 and 1a. The two bays are separated either by a wall or by a row of supporting columns. The rear bay is divided into two or more floors and these, in turn, into various rooms or compartments to accommodate the step-up transformers, switches, busbars, lightning arresters, etc.

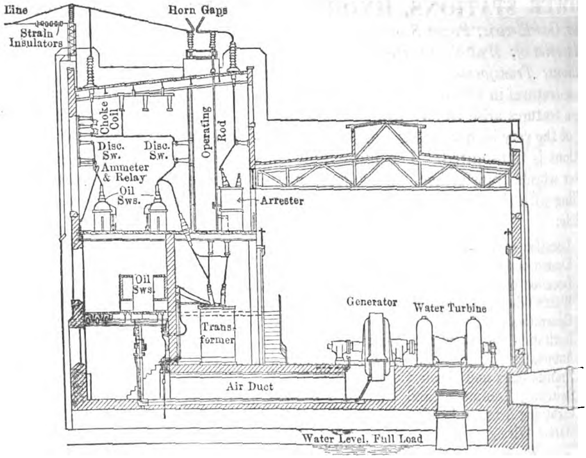

Fig. 1. Cross Section of Power House

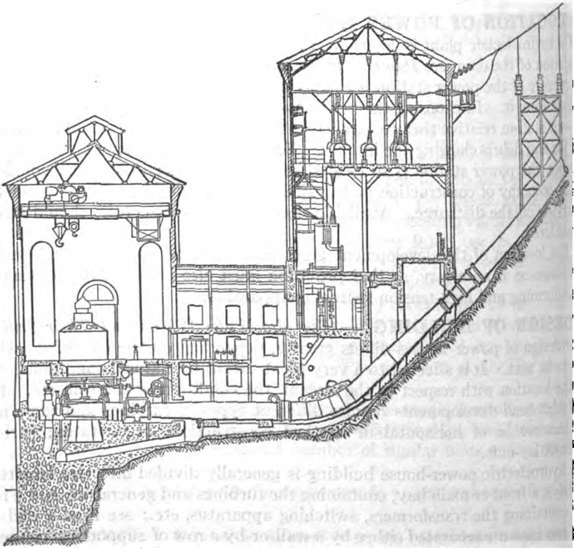

Fig. 1a. Cross Section of Power House; Roof Trusses with Raised Chord

Bearing Power of Soils. — The most important part of the building is the foundation, and careful soundings must be made to ascertain the underlying strata. If bedrock is found within moderate depth, the foundation should be carried down to the same. The safe bearing loads usually allowed for soils in this country are given in the following table:

SAFE BEARING POWER OF SOILS
(*From Baker "Treatise on Masonry Construction"*)

Material	Load in tons per sq. ft.	
	Minimum	Maximum
Rock, hardest kind	200	..
Rock, equal to Ashler masonry	25	30
Brick, equal to Ashler masonry	15	20
Brick of poor quality	4	7
Clay in thick beds always dry	4	6
Clay in thick beds moderately dry	2	4
Clay, soft	1	2
Gravel and coarse sand	8	10
Sand, fine and compact	4	6
Sand, clean and dry	2	4
Alluvial soils and uncertain sand	0.5	1

For foundations it is considered good practice to use somewhat lower values. About one-half is a good working basis for such work, thus allowing a maximum load of about 1000 lb. per sq. ft. for ordinary alluvial soils. Clean sharp sand is considered to be a good bearing soil, and it may only be necessary to cover it with a concrete mat, which requires a minimum amount of concrete. For soft or alluvial soils piling is almost always required. These may be of wood, although in the last few years much use has been made of concrete piles, both plain and reinforced. Such piles are less apt to decay and their bearing power is higher, due to their greater friction. They may also be made of larger diameters than can be obtained with wood piles and a less number is therefore required to support a given load.

Design of Foundations. — The weight on a foundation includes the machines, fittings, the weight of the foundation itself, and, in the case of the turbines, the weight due to the water thrust unless this is balanced. Separate foundations should be provided for the different units so as to isolate any failure as far as possible. Concrete is always used for the foundations.

Machinery foundations should be solid, but buildings may be supported on columns or arches so as to economize the concrete (*see Concrete*). Where there is danger of high water in the tail race, the outside foundation walls should necessarily be made water-tight so as to prevent water from entering the basement. For such cases a sump is generally provided into which the seepage may collect and from which it can be pumped out.

Basements. — A basement should be provided below the generator room when vertical turbines are to be used. That part of the floor on which the turbine discharge casings rest should be reinforced by heavy I-beams, and provision should be made for supporting the penstocks and draft tubes. There must be provided an intermediate basement floor which is generally made of concrete and should be carried on I-beams supported by the concrete piers which also support the generators and the main floor. With horizontal turbines no basement is needed. Ventilating and cable ducts for the generators,

and tunnels for piping, etc., are, however, often installed below the main floor.

Floors. — No combustible material of any kind should, if possible, be used in the construction of a power house. As the sub-structure of the building is generally built of concrete, it is but natural that the floors should also be of concrete. A dark color is preferable so as to render drops of oil inconspicuous. A tile or mosaic floor is smooth, easy to keep clean and has a very handsome appearance if made to conform with the general interior finish of the station.

Walls. — The walls may be either of reinforced concrete construction or of brick with a steel skeleton frame work. Where future extensions are contemplated a false wall is provided on one end of the building. The interior should be kept as light as possible and it is therefore advisable to apply a smooth surface of cement plaster and whitewash or paint the same. For more important stations the walls may be faced with pressed brick and up from the floor to about ten feet with enameled brick so that they may be readily washed and cleaned. Where the extra expense is warranted, the walls may be entirely lined with enameled brick and a wainscoting of contrasting color, preferably olive-green.

Roof. — The roof of the building should always be supported on the steel trusses, carried on the side walls or on steel columns. The slope should not be excessive, two inches per foot being sufficient with gravel covering. This construction requires less material, and is advantageous when the transmission wires are to enter the station through roof entrance bushings, or where the lightning arrester horns are to be installed on the roof.

The roof covering may simply consist of boards covered with roofing paper, tar and gravel. Reinforced concrete is sometimes used in place of boards so as to make an absolutely fireproof construction. Roofs covered with red tile are often used and present a very pleasing appearance. Corrugated iron roofs are objectionable due to the liability of moisture condensing on the inner surface and dripping into the station. They may also cause the station to be extremely hot in the summer unless an insulating lining is provided below the roof trusses to keep out the heat. With tile or metal roofs it is necessary to provide steeper inclines than with gravel roofs so that the water may run off rapidly. Monitors are sometimes provided so as to give additional ventilating facilities.

Roof trusses with a raised chord, shown in Fig. 1a, are in many instances of great advantage in that they provide an increased headroom without unnecessarily raising the walls of the building. This is of special importance in the high-tension part of the station, where ample headroom must be provided for the busses.

Windows. — Good lighting is imperative, and large windows are therefore essential. They should be symmetrically located with regard to the generating units and their design should be such as to harmonize with the building, arched windows being very generally used. Skylights of glass tile placed in the roof will also add considerably to the lighting. The window sashes should preferably be metallic and the glass reinforced with wire netting so as to prevent shattering when broken. Ribbed or non-transparent glass is also desirable, because it keeps out the intense rays of the sun. In order to provide for ventilation, provision should be made so that the windows can be opened, but precaution should be taken so that rain, snow or dust will not blow in on the machinery or apparatus. This is especially important on the switchboard side where the wiring is exposed and it is therefore better practice not to provide any means for opening the windows on that side. For tropical climates the windows which are liable to be opened should be equipped with mosquito screens.

Doors. — The location of the doors is naturally governed by local conditions. One of the openings should be of sufficient size to admit a railroad car, for which

tracks should be provided. Very often these doors are of the rolling type, this design being most economical as regards space.

Traveling Crane. — Provision should always be made for supporting the track for a traveling crane, which should span the generator room and run the full length of the station. The track is generally supported on pilasters in the outside wall and on the steel columns separating the generator and switch rooms. There should be ample headroom allowed so that the various machine parts can be readily removed when repairs are to be made. This is especially important with vertical units where the water-wheel rotor is mounted on the same shaft as the generator field, and in which case it should be possible to lift out the whole revolving element by simply removing the top bracket and bearing of the generator.

Miscellaneous Rooms. — Repair rooms, store rooms, offices, toilets, etc., should be provided. Ample stairway provision is essential so as to permit a ready access to important points, such as between the generator room and the switchboard gallery.

LOCATION OF APPARATUS. — The arrangement of the apparatus should be very carefully considered from the standpoint of simplicity and reliability of operation. The purpose of the station being to give reliable service consideration must also be given to the causes of disturbances and means for minimizing their effects. In anticipating these abnormal or so-called emergency conditions, the failure of every piece of apparatus must be considered as a possibility, and a definite plan worked out for limiting the magnitude and area of such disturbances.

Location of Generators. — The turbo-generator units are located on the main floor and are almost always arranged in a line along the long axis of the station. They should be spaced far enough apart so that ample space for passage is provided between them. Horizontal sets may be installed either at right angles or parallel to the long axis, the latter method being necessary for high heads where impulse wheels are used. The arrangement of the rest of the equipment, such as the transformers, may also be a determining factor in regard to which direction the sets should be installed. If one transformer bank, consisting of single-phase units, is to be installed for each generator, the space occupied by them may be of such a length that it would be more economical to install the turbo-generator sets parallel to the long axis, thus reducing the width of the building.

Location of Turbines. — (*See Water Wheels.*) With horizontal sets the turbines may be located together with the generators in the generator room or in separate wheel chambers built in the dam. The latter practice is only used for very low head developments, where one of the power-house walls forms part of the dam structure. With vertical units the turbines are always located in a basement, the thrust bearing being supported on an intermediate floor below the main floor, unless suspension bearings are used, these being mounted on top of the upper generator-bearing bracket.

Location of Exciters. — The exciters are as a rule installed on the same floor as the main generators and in the center of the station. The advantage of such an arrangement is that the exciters will be located close to the operating switchboard and the amount of copper required for the exciter leads is thus a minimum. The system may readily be sectionalized, one exciter serving the generators located in one-half of the station, and the other the generators on the opposite side. This does not, of course, refer to direct-connected exciters.

Location of Transformers. — Due to their weight, the step-up transformers should preferably be located on the main floor. They are generally installed

in isolated compartments in the rear bay, separated from the generating room by fireproof steel curtains. These compartments should be sufficiently large to allow a good ventilation. A car track is provided on the generator-room floor in front of the transformer compartments whose floors are raised so that the transformers can be run out on the car and moved to some convenient place in the station where repairs can readily be made. For large units it may be necessary to provide a hole in the floor above the repair room so as to enable the transformer core to be lifted out of the tank, or a pit may be provided into which the transformer may be lowered so that sufficient headroom is obtained for lifting out the core. Sometimes the repair room is so situated that the main crane cannot be utilized for dismantling the units. In such a case a chainfall supported from a heavy I-beam in the floor above may be provided.

Transformers Installed Out-of-Doors. — Considerable activity has recently taken place in installing transformers and associated high-tension apparatus outdoors. With the exception of the bushings the transformers for such installations differ comparatively little from the indoor type; the only feature out of the ordinary being the necessity of keeping the moisture from entering the transformer cases under the covers and leads. To prevent this the joints have been made with waterproof gaskets and breathing chambers have been provided.

Special precautions must naturally be taken to protect transformers of the outdoor type both from the extreme heat and from the cold in the winter. The former can readily be obtained by providing sunshades, and in certain instances very good results have been obtained by simply painting the cases white. It is more difficult, however, to provide for the cold winter temperatures, especially with water-cooled transformers. With the transformers in service there seems to be no danger of freezing and if such should be the case some sort of heating grids could readily be provided in the bottom of the tanks. The main difficulty lies in the formation of moisture which takes place when the temperature of the transformer is allowed to fall below that of the surrounding air; this applies also to indoor transformers. Precautions must therefore be taken that this does not happen, and may be accomplished by either reducing the water rate at times of cold weather, or by using the cooling water over and over again. Non-freezing oil may be used in such transformers, but its cost is so high that it is almost prohibitive from a commercial standpoint.

Location of Switchboards and Switchgear. — (*See also Switchboards; Switchgear Equipment for Power Stations.*) The different pieces of apparatus comprising the switching equipment are distributed on the various floors in the switch-section of the station, each story being partitioned to suit the various purposes. The operating room with the control switchboard is generally located on the second floor and in such a position that the operator may have an unobstructed view of the station, and be able to readily communicate with the turbine operators. A balcony, somewhat overhanging the generator room in front of the switchboard, is often provided or the operating room is built with a curved front wall extending out over the generator room.

Location of Oil Switches. — The low-tension oil switches are generally of the enclosed type and, together with the low-tension bus-bars (*see Bus-Bars and Bus-bar Structures*), are located generally in compartments on the main floor back of the transformer compartments. The switches themselves should preferably be set opposite the generator and transformer bank which they control, so as to call for as short a connection as possible and in order that these connections may be of equal length. The high-tension oil switches and bus-bars, and also as a rule the lightning arrester tanks, are installed on the floor above.

Disconnecting Switches. — It is customary to install disconnecting switches on both sides of an oil switch so that they may be entirely disconnected from the circuit when repairs are to be made on them, when the oil tanks are to be refilled, etc. Disconnecting switches may also be used in a number of cases for changing connections, when this is not to be made under load. Such switches should be provided with locking devices, as experience has shown that the magnetic fields caused by short-circuits may cause disconnecting switches to open, which in turn may cause serious disturbances by the arcs set up.

Spacing of Bus-Bars. — (*See also Bus-Bars and Bus-bar Structures.*) The following spacings may be used in laying out bus-bar structures:

Voltage of circuit	Distance in inches		
	Between centers of conductors of opposite polarity	Min. between live parts of opposite polarity	Min. between live parts and ground
3,300	6	2½	2
7,500	9	4	3
15,000	9	5	3½
22,000	12	7¼	6
35,000	18	12	10
45,000	24	16	14
70,000	36	24	21
90,000	48	32	27
110,000	60	38	33

Location of Lightning Arresters. — (*See also Lightning Protectors; Switchgear Equipment for Power Stations.*) The aluminum arrester is now generally used in all high-voltage stations. Both the arrester tanks and the associated horn gaps may be located within the building, or the horn gaps may be placed outside and the tanks inside, or both may be placed outside, provided there is no danger of the electrolyte freezing. Standard equipments of 27,000 volts and below are usually designed as complete units to be installed inside the station, whereas for those above 27,000 volts the horn gaps should preferably be installed outside the station and the tanks inside. Exception to this rule can be made where there is sufficient space in the station over the gaps.

The arrester tanks should naturally be located close to the line entrances. The horn gaps, when installed out-of-doors, may be placed on the roof of the building if roof-entrance bushings are used, or on a separate structure at the side of the building if wall-entrance bushings are used. The location of the arresters should also be such that the path for the discharge from the line conductors to the arresters and ground will be as straight as possible.

Clearance over Horn Gaps. — Wherever horn gaps are mounted inside the building sufficient clearance should be allowed over them. There is no appreciable arc at the gaps, but in abnormal cases where the film has been allowed to get out of order, the arc may be of considerable size. Where there are no busses or inflammable apparatus, the following are the minimum clearances from the tops of horns to be allowed:

Volts	Clearance, feet
Up to 16,100	3
16,101 to 37,900	4
37,901 to 70,000	6

These clearances should be materially increased when there are wires, cables, busses or any inflammable material over the horn gaps.

Above 70,000 volts, the horn gaps should never be placed indoors.

Effect of Climatic Conditions on Arresters Installed Out-of-Doors. — The objection to installing arrester tanks out-of-doors comes from the increased liability of freezing the electrolyte in cold weather and the abnormal film dissolution when exposed to the sun on hot days. The electrolyte may not be injured by freezing, but when frozen the internal resistance of the arrester is considerably increased and hence its discharge rate is materially lowered. Where warm climatic conditions prevail, the arrester should be in as cool a place as possible and protected from the direct rays of the sun. A high initial temperature will reduce the available heat-storage capacity of an arrester and its ability to care for long continuous discharges. A high operating temperature also increases the rate of dissolution of the films which would necessitate more frequent charging. In some cases it may be found advisable to charge two or more times a day. When operating under conditions of high temperature, any failure to periodically charge the arrester increases the liability of damage from a heavy charging current.

WATER WHEELS AND GOVERNORS. — The available types of water wheels and governors and the conditions under which they should be used are treated in detail in the articles on *Water Wheels and Their Settings*, and *Water Wheels, Speed Regulation of.*

GENERATORS AND THEIR CONNECTIONS. — (*See also Generators, Alternating-Current.*) Water-wheel-driven alternators are always of the revolving field type. Machines of this type are generally direct-connected to the water wheel. The horizontal construction has been used mostly, but recently the vertical construction has been used to a great extent, especially in low head developments. The choice is usually determined by hydraulic conditions; see *Water Wheels and Their Settings.*

Use of Power-limiting Reactances. — See article on *Reactance Coils.*

Operation of Generators in Parallel, Synchronizing, etc. — (*See Generators, Alternating-Current; Synchronizers.*)

EXCITATION AND EXCITER SYSTEMS. — It is a good practice to have the combined normal capacity of all the exciters correspond to the excitation required for all the generators, when these are operating at their maximum overload, and at the actual operating power factor. As the exciters are generally designed for a 25 per cent two-hour overload rating, a safe margin in capacity will thus be left for operating auxiliary station apparatus, such as pilot lights, switch and circuit-breaker solenoids, motors, etc. A spare unit to be kept in reserve in case of the break-down of any exciter should generally be provided. This is especially desirable where an uninterrupted service must be secured at any cost and where the exciter units are few in number, as in such a case the shutdown of one exciter would seriously cripple the system.

Amount of Excitation. — The curves in Fig. 2 give approximately the average excitation required for water-wheel-driven alternators of high and slow speeds. It is seen that, as compared to the rating of the generator, the exciter capacity ranges from 0.75 per cent for large high-speed machines to 3 per cent for small slow-speed machines.

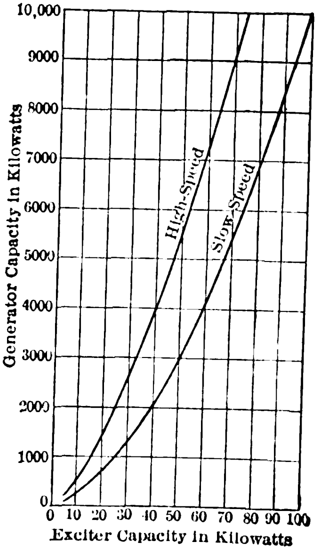

Fig. 2. Excitation Required for Water wheel-driven Alternators

"Time Element" of Exciters. — The "time element" of the exciters should be such that the insertion into its field circuit of an external resistance equal to about three times the resistance of its field circuit, will cause the voltage to drop from 125 to 25 volts in from 4 to 6 seconds. This is particularly important when automatic voltage regulators are used (*see below*), for the exciter voltage must respond quickly to the short-circuiting of the field rheostat by the regulator.

Exciter Voltage. — For large installations a 250-volt system of excitation will generally be found more economical than a 125-volt system. This higher voltage will permit the use of smaller exciter and field switches, leads of reduced size may be used between the exciters and the generator field, and the cross-section of the exciter bus-bars will be reduced. A considerable saving can also generally be accomplished in the exciter itself.

Methods of Driving Exciters. — Although the exciters can be either belt-driven or direct-connected to the machines driving them, the latter practice is almost exclusively used except in the very smallest plants. The direct connection may be either to the main generators, to separate water wheels, or to motors. Sometimes (although rarely) an exciter is connected to both a motor and a turbine, the latter running idle when the motor is carrying the load, and the motor running idle when the turbine is doing the work.

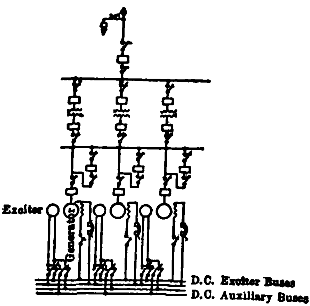

Fig. 3. Exciters Direct Connected to Main Units

Exciters Direct-connected to Main Units. — The practice of installing for each main generator an exciter direct-connected to this unit, Fig. 3, has been used to a considerable extent, especially for small and moderate-size plants. For larger installations this method is, however, now giving place to other systems. When there are not more than three main units in the station, each of the direct-connected exciters should preferably have a capacity sufficient to excite two of the units, so as to provide for reserve in case of damage to one of the exciters. With more than

three units, there seems to be no reason why extra capacity should be provided, and any reserve capacity is then best provided by installing a motor-generator set.

Three-exciter System. — The system which is the most widely used and which offers the greatest reliability, is that in which the excitation is obtained from a common source, consisting of as few exciters as possible, Fig. 4. Three units are then generally provided, of which two are all that are needed for supplying the required excitation, the third unit being held in reserve. Sometimes the two exciters normally in service are driven by water wheels, the reserve unit being motor-driven. From the point of view of economy, however, it is evident that two motor-driven units with a water-wheel driven set as the spare will cost less. In the latter case, however, the exciter trouble with the exciter driven by the prime mover would prevent starting up the system, unless a storage battery were provided, which, however, is usually the case in large stations.

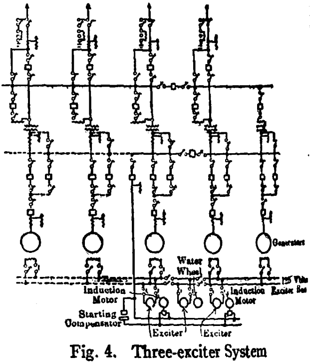

Fig. 4. Three-exciter System

Individual Motor-driven Exciters. — In some of the latest hydro-electric developments an entirely new and quite novel system of excitation is being used, one small motor-driven exciter set being installed for each generator unit, Fig. 5. The exciter has a capacity corresponding to that required by its generator, and its terminals are connected directly to the generator field. The motors of the various exciter sets are fed from one or two low-voltage generators, driven by independent turbines. In addition, means are provided so that if necessary the motors may be connected to the main bus through transformers, two separate sources being thus provided for driving them. This arrangement avoids the objection to motor-driven exciters on the ground that they are liable to fall out of step when a short-circuit occurs on the system.

Electrical Connections of Exciters. — The general practice is to provide one or two sets of common bus-bars to which all the exciters are connected in parallel and from which the fields of the different generators are excited, a rheostat being inserted in each field circuit.

Exciters Direct-connected to Main Units. — The diagram shown in Fig. 3 represents a system where every generator is provided with a direct-connected exciter. There are two sets of bus-bars, one for excitation and the other for auxiliary service. Switches are provided so that the exciters can be connected to either set as desired. The advantage of this system is that one exciter can be connected to the auxiliary bus while the others are operating on the exciter bus. Any fluctuation in the exciter voltage caused by an automatic regulator, for example, will therefore not be felt on the auxiliary or lighting bus, the pressure of which can be kept constant.

Three-exciter System. — The arrangement shown in Fig. 4 is often used for the exciter system when a combination of motor-and water-driven exciters is used. Only one set of exciter bus-bars are shown, although frequently an auxiliary set is also provided as in the previous case. There are e exciters, two of which are driven by induction motors fed from the main

bus-bars, and the third unit, which is held in reserve, is driven by an independent water wheel. Only one starting compensator is needed for the two motors, a common starting and running bus being provided. The system can be sectionalized in two parts if desired, and switches are provided so that the water-wheel-driven exciter can be connected to either side.

Individual Motor-driven Exciters. — Fig. 5 represents the practice when an individual motor-driven exciter is used for each main unit. Each exciter is connected directly to the field of its respective generator. The exciters are not arranged for parallel operation, but are each provided with its own automatic regulator, so that it is possible to compensate for "wattless" or reactive cross-currents between the generators. In the system shown, the induction motors are fed either from two low-voltage alternating-current generators driven by separate water wheels, or alternatively from the main alternating-current bus-bars through stepdown transformers. The auxiliary low-voltage generators are the normal source; the exciter system is thus entirely free from voltage fluctuations or disturbances on the alternating-current system. In another installation of this kind the auxiliary generators are provided for combination drive, one end being connected to a water wheel and the other to an induction motor, which in turn can be connected to the main alternating-current busses through stepdown transformers, unless the voltage will permit of a safe operation of the motors without the transformers. In such an arrangement the exciter sets are not provided with independent group connections to the main bus, as shown in the illustration, as it is considered that a breakdown would most commonly be caused by a clogging up of the turbines, in which case the alternating-current units could be driven by the motors. It would seem, however, that the scheme shown in the diagram is more flexible and reliable.

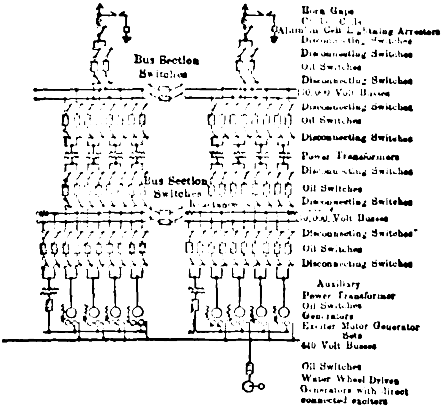

Fig. 5. Individual Motor-driven Exciters

Storage Battery on Exciter Bus. — The use of storage batteries in connection with exciters has been increasing of late. The advantages of such a combination is obvious, as with the failure of the exciters for any reason, the storage battery would automatically keep up the excitation. The storage battery is generally floating on the exciter busses, the pressure of which is kept constant. A separate exciting bus is provided and between this bus and one of the exciter bus-bars a booster is installed which can be operated to either raise or lower the voltage, its field being controlled by an automatic voltage regulator. In case of failure of the exciters the excitation would be furnished by the storage battery, and the booster in connection with the regulator would take care of the voltage regulation.

AUTOMATIC VOLTAGE REGULATION. — Without some form of automatic voltage regulator it is impossible to take care of the heavy swings in the voltage caused by fluctuating power and railway loads. Even in the case

of a purely lighting load it is exceedingly difficult to properly take care of the voltage by hand regulation, especially at peak loads. The present tendency of designing generators for a high internal reactance, in order to reduce destructive short-circuit currents, results furthermore in a rather poor inherent regulation of the generators.

Many different forms of automatic regulators have been devised. Some of them have been designed to operate directly on the alternating-current generator field rheostat by varying the resistance. Such a system has, however, proved to be entirely too sluggish in operation. The most successful type of automatic regulator is the T. A. Regulator in which the regulation is effected entirely in the field circuit of the exciter, by rapidly opening and closing a shunt circuit across the exciter field rheostat. See the article on *Regulators.*

TRANSFORMERS AND THEIR CONNECTIONS. — (*See also article on Transformers.*) The number and size of the transformers depends entirely on the nature of the development and on the conditions to be met. With a moderate voltage development it has in the past been the general practice to install one transformer bank for each generator and having a capacity equal to that of the generator, even if this size was not the most economical. For present modern high-voltage systems where it is undesirable to parallel transmission lines on the high-tension side, or to carry out any high-tension switching, it has become general practice to install the transformers in groups, each having a capacity corresponding to the line, the transformer group and the line thus being considered as a unit. Transmission lines generally have a carrying capacity ranging from 15,000 to 40,000 kw. As the most economical size of high-voltage transformers is from 6000 to 10,000 kw., it is entirely feasible to provide one bank of single-phase transformers for lines up to about 25,000-kw. capacity; but above this capacity it, as a rule, becomes necessary to provide two banks in parallel for each line.

In order to facilitate moving the transformers in or out of their compartments, wheels should be provided in the base or trucks may be installed on which the transformer will rest. The design should also preferably be such that the complete core and coils, with the cover and leads can be lifted from the tank as a unit. Eyebolts are provided for this purpose and also for lifting the entire transformer filled with oil.

Single- versus Three-phase Transformers. — No specific rule can be given regarding the selection of single-phase or three-phase transformers since both designs are equally reliable; local conditions will generally determine which type is preferable. See the article on *Transformers.*

Use of Auto-Transformers. — (*See also Auto-Transformers.*) Auto-transformers are sometimes used in connection with Y-connected generators for obtaining a moderate rise in the voltage. Where such is the case a path must be provided for the flow of the triple-frequency exciting current, which is required for the normal magnetizing of the transformer. With a grounded generator neutral (*see Generators, Alternating-Current, and Grounding of Electric Circuits*), this can be obtained by also grounding the neutral point of the auto-transformers, although it is also highly desirable to connect the two neutrals together as any ground offers more or less of a resistance. If a sure path for the triple-frequency exciting current is not provided, a third harmonic will appear in the no-load e.m.f. from line to neutral and cause an excessive strain in the windings, which under such conditions should in all cases be insulated for a higher voltage than the normal.

Cooling of Transformers. — Transformers for hydroelectric generating stations should obviously be of the water-cooled type. Ordinarily the water

rate to keep a transformer of this type cool is approximately one-half gallon per minute per kw. loss, the temperature of the incoming water being 15° C.

Cooling coils are generally made of extra heavy lap-welded wrought iron pipe with electrically-welded joints. These coils will withstand a hydraulic test of 1000 pounds per square inch. In some cases the quality of water available for cooling purposes may make it necessary to use either brass or copper pipe, in order to avoid corrosion which would prohibit the use of iron pipe.

Drying of Transformers. — It was formerly customary in shipping transformers to pack the cores separately from the tanks. Where the railroad clearances will permit, transformers are now shipped assembled with the oil in the tanks, the cores being securely braced in the tank. In this manner the transformers should arrive at the destination with the insulation and oil practically dry and free from moisture. Where transformers are shipped without the oil in the tanks it is almost invariably necessary to dry them out first. This may be accomplished in several ways, as explained in the article on Transformers (q.v.).

Transformer Oil. — The oil, whether shipped in the transformer case or separately, should always be tested before it is used in service (*see the article on Oil, Transformer*), and should be dried if it punctures at too low a voltage. Oil for transformers of 40,000 volts and over should be dried before using, if it punctures below 35,000 volts. For transformers having voltages less than 40,000 volts, the oil must be dried if it punctures below 25,000 volts. Where oil is dried it may easily be brought to a puncture of 40,000 volts. If a sample contains sediment, it will puncture at a lower voltage than it would without the sediment.

Transformer Connections. — With the three-phase system the transformers are usually connected in delta or Y, and when the Y-connection is used the neutral may be grounded or not. It is a much-disputed question which connection is to be preferred. In general it may, however, be said that in transmission systems where continuity of service is the most important factor, delta-connected transformers (both primary and secondary) are preferable on account of the increased reliability which such a system affords. See articles on *Transformers* and *Grounding of Electric Circuits*.

For high-voltage systems it is, however, now being generally conceded that the Y-connected system with the neutral grounded is preferable, if not almost essential. The fact that any ground will then constitute a short-circuit followed by a shut-down, is outweighed by the limitations of the rise in voltage caused by such grounds. Modern transmission line apparatus must furthermore be designed to withstand the mechanical strains imposed by short-circuits. With a ground on a delta-connected system it is evident that the neutral is shifted from the center of the delta to one corner, and the charging current, which is a function of the voltage from wire to neutral, is therefore increased in proportion, or about 73 per cent. This increased charging current will in turn cause a corresponding increase in the voltage rise which may take place when the lines are cut in circuit at no load. Actual experience has shown that this voltage may reach prohibitive values which, of course, would not be the case with the Y-connected, grounded system.

SWITCHING EQUIPMENT AND ELECTRICAL CONNECTIONS. — Continuity of service is the most essential part in the protection and operation of a large high-tension power system. A maximum degree of reliability can naturally be obtained by providing reserve and duplicate apparatus, the maximum reliability thus being governed by the permissible investment in the apparatus, by the price paid for the power and by the competitive situation.

In small and medium-size power plants the switching equipment may be of the hand-operated type, mounted directly on the back of the switchboard panels

or on a separate framework and operated by hand by means of levers located on the front of the panels. For large modern power houses the switches should, however, always be of the remote control type. The control board is then located so that the operator may obtain the best view of the station, while the switches and bus-bar structure are installed with regard to convenience of wiring and safety.

The switch and bus-bar structure for large stations may be either of the enclosed or open type, but is mostly a combination of the two.

The entire subject of switchgear equipment is discussed in detail in the separate article on *Switchgear Equipment for Power Stations*, which see.

Sectionalized Low-tension Bus. — (*See also Bus-Bars and Bus-bar Structures.*) The generators should preferably be paralleled on a low-tension bus, and where the total capacity is large the bus should be sectionalized, it being the general practice to limit the normal capacity of each section to from 30,000 to 50,000 kv-a. The sections may be connected by means of automatic switches provided with instantaneous overload relays which in case of trouble in one section will immediately disconnect the same from the other sections and thus limit the power which the oil switches will have to rupture to the capacity of one section. In some of the recent systems reactance coils have been inserted between the bus sections, and the sectionalizing switches have been made non-automatic. The reactances generally have such a value that on short-circuit in one section they will limit the total power rush from the two adjacent sections to the short-circuit current of one generator.

In sectionalizing the bus it is desirable to make such provision that sufficient generator capacity to supply the charging current of one transmission line can be entirely separated from the rest and used for testing out the lines. A ring bus will generally insure sufficient flexibility to accomplish this, although for large systems a double bus may be desirable if the extra expense is warranted.

Generator Switches. — The generator switches are usually made non-automatic, as it is of the utmost importance to keep the generators in service, and the possibility of trouble between the generators and busses is rather remote. If, however, automatic protection is desired for the generator switches, the relays (*see Relays*) should be of the definite-time limit type, set very high so as to trip the switches as a last resort, after the automatic switches more remote from the generators have failed to isolate the trouble. Sometimes the generator switches are provided with reverse energy relays which will cut out a damaged generator on the reversal of the power, or the relay may be connected to an alarm bell which will indicate such a condition.

Transmission-line Connections. — (*See also Transmission Lines.*) Double transmission lines are nearly always provided to important load centers, and it is then also desirable to so proportion the line conductors that in case of trouble, one line alone or together with a section of the other can take care of the greater part of the load without causing too poor a regulation. The lines should normally be operated electrically apart from each other, the paralleling and switching being done on the low-tension side of the transformers in both generating and substations. This is in order to avoid high-frequency surges caused by high-tension switching, and also to prevent communication between the lines of disturbances started from any other cause, such as lightning, arcing grounds, etc.

All feeder switches should be provided with instantaneous overload relays (*see Relays*) as it is of course necessary to immediately cut out any damaged feeder and confine the interruption to the smallest area possible.

The diagram of Fig. 6 represents a system in which each transformer bank forms a unit with one line. The high-tension line switches L_9 and L_8 are non-automatic and are only intended for sectionalizing purposes, as are the tie

switches S which should be open under normal operation. The transformer switches T_g and T_s in the generating and substations respectively should be of the automatic type, the former being equipped with inverse time-limit relays and the latter with reverse-energy relays. A short-circuit in one of the lines will cause switches T_g and T_s, belonging to this circuit, to open, thus disconnecting

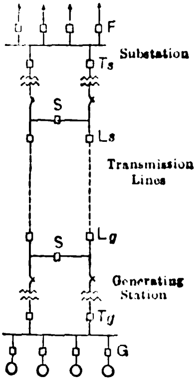

Fig. 6.

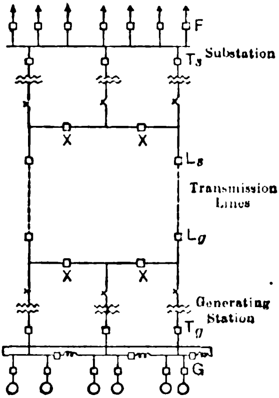

Fig. 7.

it from the system. The load is then shifted over to the other line which remains in service, and may overload the transformers of this line. This will not cause any danger, as the transformers can readily carry up to 100 per cent overload for a few minutes until the operator has had time to open switches L_g and L_s, disconnecting the faulty line from its transformers, and close switches T_g, T_s and S, connecting the transformers in parallel again.

In the system represented in Fig. 7 three transformer banks are provided with only two lines. The connections are similar to those in Fig. 6 except that the high-tension side of the third transformer bank is connected to the outgoing lines through the oil switches X. These should be of the automatic type provided with instantaneous overload relays. A short-circuit in any of the lines will thus cause these switches to trip out with a comparatively small disturbance, after which switches T_g and T_s will open, disconnecting the damaged line.

LIGHTNING ARRESTERS, EQUIPMENT AND CONNECTIONS.— Aluminum cell electrolytic lightning arresters are now used almost entirely for lightning protection of high-voltage transmission systems, see article on *Lightning Protectors*, for description of the various available types of arresters. The arrester, however, is not a universal protector against all kinds of interruptions. For example, while it meets the usual, and most of the unusual, needs in protection against disruptive potentials from lightning, an arrester located in the station cannot, and is not expected to, protect an insulator out on the line from a lightning flash. Neither is it designed to protect against surges of comparatively low voltage.

Arresters for Grounded and Ungrounded Circuits.—It is important to avoid the mistake of choosing an arrester for a thoroughly-grounded neutral when the neutral is only partly grounded; that is to say, grounded through an appreciable resistance. In an arrester for a grounded neutral circuit, each stack of cones normally receives the neutral potential when the arrester discharges;

but if a phase becomes accidentally grounded the line voltage is thrown across each of the other stacks of cones until the circuit breaker opens the circuit. Line voltage is 173 per cent of the neutral or normal operating voltage of the cells and therefore about 150 per cent of the permanent critical voltage of each cell. This means that when a grounded phase occurs this 50 per cent excess dynamic potential is short-circuited through the cells until the circuit breaker opens. The amount of energy to be dissipated in the arrester depends upon the kilowatt capacity of the generator, the internal resistance of the cells and the time required to operate the circuit breakers. It is evident that the greater the amount of resistance in the neutral, the longer will be the time required for the circuit breakers to operate. Therefore, in cases when the earthing resistance in the neutral is great enough to prevent the automatic circuit breakers from opening practically instantaneously, an arrester for a non-grounded neutral system should be installed. It is difficult to determine these factors of ground resistance and time elements in the operation of switches and therefore no mistake can be made by adopting the 4-tank arrester even on grounded Y circuits.

Wiring Connections for Lightning Arresters. — The wiring connections of lightning arresters are an important consideration. The discharge circuit should contain minimum impedance and hence must furnish the shortest and most direct path from line to ground. The most severe disturbances which an arrester is called upon to handle are of high frequencies and it is, therefore, imperative to eliminate all unnecessary inductance. The features favorable for low inductance are short length of conductor, large radius bends and large surface of conductor. For wiring high-voltage arresters the use of copper tubing is therefore recommended. Such copper tubing has the advantage over either copper-strip or solid conductors in that it is easily supported, requires fewer insulators and is, therefore, cheaper to install. From arrester to ground it is sometimes more convenient to use copper strip than tubing. Copper strip, say 1.5 in. by 0.03 in., can be fastened to the station wall leading directly down to ground.

Ground Connections for Lightning Arresters. — In all lightning-arrester installations it is of the utmost importance to make proper ground connections since many lightning-arrester troubles can be traced to bad grounds; see article on *Ground Connections*. As noted in the article referred to, a very satisfactory method of making a ground is to drive a number of one-inch iron pipes six or eight feet into the earth about the station, connecting all these pipes together by means of a copper wire, or preferably, by a thin copper strip. A quantity of salt should be placed around each pipe under the surface of the earth and the ground thoroughly moistened with water. It is advisable to connect these earth pipes to the iron framework of the station, and also to any water mains, metal flumes or trolley rails that are available. For the usual size station the following recommendation is made: place three earth pipes equally spaced near each outside wall, making twelve altogether, and place three extra pipes spaced about six feet apart at a point nearest the arrester. When plates are placed in streams of running water, they should be buried in the mud along the bank in preference to laying them in the stream. Streams with rocky bottoms are to be avoided.

From time to time the resistance of these ground connections should be measured to determine their condition; see article on *Ground Connections*. The resistance of a single pipe ground in good condition has an average value of about 15 ohms. A simple and satisfactory method of keeping account of the condition of the earth connections is to divide the earth pipes into two groups and connect each group to the 110-volt lighting circuit with an ammeter in series. If there is a flow of about 20 amperes the conditions are satisfactory, provided the earth pipes are properly distributed around the station.

Charging of Aluminum Cell Arresters. — This is accomplished as follows:

First. — Operate the charging mechanism so as to bring the charging contact securely against the horn gap and charge for five seconds. The contacts should be so adjusted as to eliminate arcing when gaps are closed. The closing and opening of the charging contact should be performed quickly so as to avoid unnecessary arcing. Note should be made of the size and color of the arc which forms when the contact is broken at the close of the charging period.

Second. — With the horn gaps in normal position reverse the transfer device, thereby interchanging the connections to the ground stack of cones and one of the line stacks.

Third. — The first operation should again be repeated, thus charging the fourth stack of cones, which was originally the ground stack.

When an arrester is first installed and also when one has been off the circuit for several days the initial charging current is sometimes above normal. It is recommended that the cells be charged six or eight times the first day and three times a day during the remainder of the first week. This charging should be performed as just described. After the first week the regular daily charging will usually be found sufficient. It is important that the charging should be done at a time of the day when the line voltage is at a maximum value. The charging period should always be five seconds.

In cases where aluminum lightning arresters are installed in places where the temperature is excessive, it is sometimes advisable to charge the arresters twice a day. This condition will be indicated by an increase in the charging arc and charging current from day to day.

Charging-current Indicator. — The charging-current indicator is a device for measuring the current taken by an alternating-current aluminum arrester during charging; it also indicates the condition of the arrester cells. An arrester in good condition has a charging current of approximately 0.25 ampere on 25-cycle circuits, 0.30 ampere on 40-cycle, and 0.40 ampere on 60-cycle circuits. Should these values be doubled, the arrester must be charged more frequently and the current carefully measured until it comes down to normal. It is only when this additional charging fails to reduce the charging current that an inspection of the cells is necessary.

The essential parts of the charging-current indicator are an ammeter mounted on a specially-constructed switch stick and a set of jacks. These jacks are so connected in the arrester circuit that when the ammeter switch stick is inserted in them and the horn gaps short-circuited, the charging current flows through the meter.

Discharge Recorders. — A knowledge of all discharges is of immense value to operating engineers in studying conditions of abnormal voltage on transmission and cable systems. For this purpose a discharge recorder has been developed, which will register the time and nature of discharges through an arrester. This recorder consists of four spark gaps so arranged that the discharges between lines or between lines and ground pass through the gaps. The spark gaps are assembled with a clock-operated drum in such a manner that a continuous record is obtained, showing all discharges by means of punctures in a moving roll of paper. This paper passes through the gaps at a rate of about one inch per hour which gives an accurate record of the time and duration of each discharge.

Besides being valuable in recording discharges due to abnormal voltages on a system, the discharge recorder is of value in indicating and recording the daily charging of the lightning arresters. With such a recorder it can be told whether the arresters are or are not being properly charged by the station operator; and besides, the puncture gives some indication of the condition of the arrester.

Choke Coils. — Choke coils should always be installed in the power circuit between the lightning arrester and the apparatus to be protected. All choke coils should be very rigidly supported as they are subject to severe mechanical strains when short-circuits occur on the system. See article on *Lightning Protectors*.

Use of Arcing Ground Suppressor. — This apparatus is described in the article on *Ground Detectors and Arcing Ground Suppressors*. One arcing ground suppressor is sufficient for controlling the entire system. When several power stations feed into one transmission system special attention should be given to the best location of the suppressor.

STATION WIRING. — The design and construction of the cabling and wiring system of the station is of equal importance to the rest of the equipment. Experience has shown that in a great number of instances the shut-down of power plants was caused by defective installation of the station wiring. Every cable and wire should have a definite place provided for it in advance, just as much as any other piece of machinery, and wires carrying currents of different voltages should, as far as possible, be kept apart from each other.

Braided vs. Lead-covered Cables. — For generator and low-tension transformer leads, braided or lead-covered cables are used, and may be run in ducts or exposed upon racks in cable-ways or tunnels. Lead-covered cables are necessarily more expensive than braided cables, and their use seems to be justified only in places where protection against water and moisture is required. As the lead sheath is necessarily grounded along its entire length, such cables are more apt to be punctured. As a protection against fire the lead covering is obviously useless and due to its softness it is not very efficient in withstanding mechanical injuries.

Installation of Cables. — (*See also article on Wires and Cables, Insulated.*) In many plants the cables are installed in ducts in the floor, and in such instances the cables should preferably be lead-covered to protect the cables from abrasion when drawn into the ducts. There are, however, several other objections to installing the cables in ducts. With high-voltage single-conductor lead-covered cables, static discharges may take place through the insulation to the lead, which rapidly injures the insulation and a breakdown soon follows. If the cable is not lead-covered a static discharge may take place to the tile duct, this also having a tendency to break down the insulation in time. In multiple-conductor cables this action does not occur, the static activity probably being neutralized. With cables carrying large low-voltage currents the lack of ventilation in the ducts may furthermore cause overheating of the cables.

In a large number of stations the open method of cabling is used. Tunnels or cable subways are then provided in which braided cables are supported in free air upon insulators mounted on racks, these insulators themselves having sufficient insulation to withstand the operating voltage of the cable. Where single-conductor, high-voltage cables are used, they should be separated far enough to prevent static discharges between the cables, and also in order to obtain the best possible ventilation and to minimize trouble in case of short-circuits. The cables should also be rendered fireproof by wrapping them with asbestos tape.

Size of Cables. — Due to the skin effect it is generally considered good practice to limit the size of single-conductor cables to 1,250,000 cir. mils for 25-cycle service and 700,000 cir. mils for 60 cycles. Where the value of current is such that it can be carried safely by one three-conductor cable, this is preferable in every respect to three single-conductor cables. If more than one cable has to be used to carry the current the difficulty of making connections will generally offset the advantages of three-conductor cables, and under such conditions it is usually found to be more advantageous to use single-conductor cables.

High-tension Wiring. — Bare wire or tubing supported on post insulators or hung from suspension insulators is generally used for all high-tension wiring. High-tension station wiring is described in detail in the article on *Switch-gear Equipment for Power Stations.*

OPERATION AND OPERATING RECORDS. — The selection and maintenance of an efficient and reliable operating force is essential. Most modern systems of any size have a method of operation which corresponds to that of a train dispatcher on steam railroads, and where many different plants are attached to the same network, this becomes practically necessary. The directions for operating the different stations and apparatus come from a central source, where the dispatcher has before him a diagram of the whole system and information regarding the capacities of the generators in use and the magnitudes of the loads at the different places of distribution.

Organization of Operating Force. — The organization of the operating force of a hydroelectric generating station is necessarily less complicated than in a steam station. It is determined largely by the location and the arrangement, and there are so many different conditions in such systems that it is impossible to recommend any exact form of organization, as really no two can be quite alike If the station is not too large, it is desired to have the hydraulic superintendent report to the station superintendent, but if the development is of such a magnitude as to require the entire time of a superintendent for each of the departments under consideration, a position is warranted for a man to whom both electric and hydraulic superintendents will report, thus still bringing the responsibility of operation of the two departments under one head.

As a general rule, for the same capacity installed, a plant having horizontal units can get along with a smaller force than one using vertical units. It is a general practice to maintain one man at all times on each of the different levels or floors of the power house, such as the switchboard gallery, the main floor and the basement, where with vertical units the turbines proper as well as the oil pumps and other auxiliaries are located. The man in the basement could in all probability be dispensed with in plants using horizontal units. In addition to these men a chief operator should be provided for each shift, whose duties should carry him to all parts of the building. For a very large station the above force may be entirely inadequate, and for small plants the force may be reduced.

Switching Operations. — The switching operations are determined by the general method of operation. It is desirable to eliminate all high-tension switching under load, due to the fact that such switching may set up surges which may be dangerous to the transformers and other apparatus.

When a line is to be cut into service, the high-tension switches in both the main and substations should be closed first, then the low-tension transformer switch in the generating station should be closed, energizing the transformers and the line, after which the low-tension transformer switch in the substation is closed and the load picked up. In case it becomes necessary to open a high-tension switch in a loaded line, the circuit should if possible first be parallel with another before opening the switch. If, on the other hand, transformers are to be paralleled on both high- and low-tension sides, the low-tension switch should be closed first, assuming that the low-tension bus is energized. Similarly, in cutting out the transformer the low-tension switch should be opened last.

Operating Records. — One of the essential things in connection with the operation of hydroelectric generating stations is the keeping of accurate records. Record sheets should contain only the most important readings, as with complicated forms the attendant generally realizes that a large number of the readings are of no importance and for this reason he becomes very lax in his attention to the readings in general and as a consequence the important ones may suffer

The following description applies to an actual record sheet which has been found to give satisfactory results. The sheet is of the size of ordinary letter paper and is ruled for hourly records of "Water," "Main Units," "Cycles," "Power Factor," "Exciters," "Transformers" and "Floodgates." These items are listed vertically and the sheet is divided into 24 vertical columns, one for each hour. At the top are given the "Forebay" readings and "Tail Race" readings, the difference between which gives the "Effective Head." Immediately below are listed the indicated kilowatts and per cent gate opening of each generator in service, following which are given the "Total Indicated Kilowatts" and "Total % Gate." The total kilowatt-hours during each hour, as read from the watthour meters, is plotted as a block-curve extending across the face of the sheet.

This serves as a better record for the actual station output than the indicated kilowatts. It has been found necessary, however, to follow the indicated kilowatts to serve as a check on the efficiency and condition of the units in general, from time to time, as well as to determine what capacity would be required for short interval peaks. The station voltage is also plotted as a block curve across the face of the sheet.

The exciters form an individual group, and for each exciter the voltage, current and per cent gate opening are recorded.

Transformer records are limited to the temperatures. These are taken hourly, at which time the oil elevation is noted but not recorded. If the transformer is not in service the column in which the temperature is listed is left blank; if in service the temperature is taken and recorded.

Under the item, "Floodgates" the total opening of the floodgates in feet is recorded, rather than each one separately. This record is maintained daily, the flow of the river at each of the stations being followed very closely.

At the bottom of the sheet appear the daily readings of the various generator and feeder watthour meters taken at midnight of each 24 hours. The following items are also recorded at the bottom of the sheet: "Total Generated," or the total output of the station for 24 hours; the "Maximum Hour Time," or the maximum kw-hr. of any particular hour during the day; the "Maximum Kw. Time," or the maximum indicated kilowatts at any particular instant; the "Average Load," obtained by dividing the total kilowatt hours generated by 24; the "Load Factor," obtained by dividing the "Average Load" by the "Max. Kw. Time"; the "Average Flow of the River in Cubic Feet per Second," calculated each day and converted into "Available Capacity of River," which is shown in kw-hr.; the "Available Capacity of Power House," shown in kw-hr., and determined by calculating the capacity of the machines under the average head for 24 hours; the "Kw-hr. Lost," or the difference between what was actually generated by the machines and what could have been secured from the river during the same number of hours.

Any important notes of operation are entered on the back of each day's log sheet. These notes, together with certain records for log sheets, are also entered each day in a log book kept on the operator's desk at all times, for reference purposes. Weather conditions and temperatures are recorded four times daily, at midnight, 6 A.M., noon and 6 P.M. A rain gauge is provided on the roof of the station, from which records of precipitation covering each 24 hours are obtained

CAPITAL COSTS AND APPROXIMATE DIMENSIONS. — (*See also section below on Capital and Annual Costs of Some Typical Plants.*) The cost of a large water-power development is generally very great. The estimates of the amount of power available are always subject to error and many times are greatly exaggerated. On account of unforeseen obstacles in dam construction, it is always possible that the actual cost will exceed the engineering estimates, and

such elements of uncertainty must always be taken into consideration. Moreover, as the large water powers of the country are generally more or less remote from power markets, there is necessitated the construction of expensive high-tension transformer equipments and transmission lines to transmit the power to the point of consumption. This additional cost is often greater than that of the dam and power-house construction. The provision of large storage reservoirs is often necessary in order to meet the irregularities in the flow of streams, while, on the other hand, the most economical utilization of water power often requires the erection of auxiliary steam plants.

The main items entering into the cost of construction of a hydroelectric power plant are: (1) Dam, (2) Water Conductors, (3) Reservoirs, (4) Power house, (5) Land and Water Rights, (6) Transmission Lines. In addition to the cost of the above physical equipment certain overhead and organization expenses must also be included. These may be classified as follows: (7) Engineering and Contingencies, (8) Administration, (9) Organization, (10) Taxes and Insurance, (11) Interest during Construction, (12) Working Capital.

Range of Total Capital Cost per Horse-Power. — Extensive investigations by the Bureau of Corporations show that the cost of a hydroelectric power development, including the construction of dams, the erection of transmission lines and other equipment, ranged from $50 to $375 per horse-power delivered at the substations. These figures represent extremes, as the usual cost will fall between $100, and $200 per horse-power, depending upon physical conditions and the length of the transmission lines.

Approximate Dimensions and Construction Costs. — It is obvious that there are certain minimum costs that can readily be approximated when the rough dimensions of dams, pipe lines, etc., are available, so that rough minimum figures can readily be made. Such rough figures cannot be expected to take into account expensive contingencies that must be anticipated.

Dams. — Given the length and height of dam, the dam structure itself will have a cost of material that can be estimated roughly, and the ordinary cost of placing such material — including tools and forms — can be added, but the extraordinary labor costs due to the construction of expensive foundations and coffer dams and the cost of placing dam material under difficult conditions can, of course, only be estimated by experienced engineers thoroughly familiar with the local conditions.

Expressing the height of dam in yards as h, the approximate sections of dams and approximate costs of dams not used as weirs or spillways are:

SECTIONS AND COST OF DAMS NOT USED AS SPILLWAYS

Type of dam	Batter or slope: Common upstream batter horizontal to vert.	Batter or slope: Common down stream batter	Approx. section in sq. yards	Approx. cost per cubic yard	Approx. cost per lineal yard
1. Earth	2 to 1	3 to 1	$2.5h^2$	$0.50	$1.25 h^2
2. Crib	1½ to 1½	1½ to 1	$1.5h^2$	1.50	2.25 h^2
3. Rock fill	2 to 1	2 to 1	$2.0h^2$	2.00	4.00 h^2
4. Masonry, straight	Vertical	8/10 to 1	$\frac{4}{10}h^2$	12.00	4.80 h^2
5. Masonry, arched	0.15 to 1	0.30 to 0	$\frac{1}{4}h^2$	15.00	3.50 h^2

It should be borne in mind that maintenance and depreciation on Types 1, 2 and 3 are far heavier than on Types 4 and 5.

These figures are intended to cover all costs under ordinary conditions, for the cost per cubic yard is taken sufficiently high; but they cannot be used for extraordinary conditions, producing costs possibly four or five times greater.

Low crib or masonry dams used practically throughout their length as weirs or spillways may easily cost many times these figures.

No figures are given for intakes, owing to the great variety of conditions to be met.

Flumes. — The use of flumes of wood becomes less and less as hydroelectric work becomes more permanent in character. For estimate purposes it is then suggested that the cost of wood-stave or riveted-steel pipe be used instead of using the presumably lower cost of the flume. It is obvious that repairs and depreciation on flumes are heavy, and hence they would seem to have little use in permanent construction.

Low-pressure Pipes. — (*See also Pipes and Piping.*) In hydroelectric work cast-iron pipes are seldom used. Wooden-stave and riveted-steel pipes have been widely used for low pressures. The approximate costs of these, as compiled by A. L. Adams for Chicago, are given in the following tables.

COST PER FOOT OF WOODEN-STAVE PIPE

Including laying but omitting hauling

Diameter in inches	25-foot head	50-foot head	100-foot head	200-foot head
12	$0.42	$0.49	$0.63	$0.85
18	0.69	0.80	1.02	1.46
24	0.79	0.91	1.14	1.61
30	0.96	1.12	1.44	2.06
36	1.19	1.40	1.82	2.65
42	1.40	1.68	2.23	3.33
48	1.55	1.85	2.46	3.67
54	2.23	2.62	3.43	5.02
60	2.85	3.35	4.37	6.40
66	3.21	3.81	5.00	7.38
72	3.65	4.38	5.83	8.73

COST PER FOOT OF RIVETED-STEEL PIPE

Including laying but omitting hauling

Diam. in in.	No. 14	No. 12	No. 10	No. 8	No. 6	1/4 in.	5/16 in.	3/8 in.
12	$0.32	$0.38	$0.44	....	....	....	....	....
18	....	0.57	0.65	$0.78	$0.98	....	....	....
24	....	....	0.85	1.04	1.28	$1.55	$1.99	....
30	....	....	....	1.27	1.59	1.93	2.46	$3.04
36	....	....	....	1.55	1.93	2.30	2.92	3.58
42	....	....	....	1.61	2.18	2.66	3.37	4.12
48	....	....	....	....	2.48	3.03	3.83	4.66
54	....	....	....	....	2.80	3.41	4.29	5.21
60	....	....	....	....	....	3.79	4.75	5.74
66	....	....	....	....	....	4.35	5.21	6.29
72	....	....	....	....	....	4.52	5.66	6.83

High-pressure Piping. — In high heads the high-pressure piping may be either riveted-steel pipe or lap-welded pipe with bolted flanged joints. It is suggested that a percentage amount be allowed for this, as the cost must vary widely for different conditions.

Tunnels. — Tunnels for hydroelectric work are usually lined. Naturally the cost per cubic yard varies, but for ordinary conditions an average unit cost of $15 per cubic yard will cover all expense including timbering and lining. Allowing a velocity of 10 ft. per second (except in the smallest tunnels), approximate dimensions and costs are as follows:

COST AND DIMENSIONS OF TUNNELS

Carrying capacity in cubic feet per second	Velocity in feet per second	Net sectional area, square feet	Dimensions in feet, width by height	Approximate slope, feet per 1000 feet	Approximate cost per linear foot
100	3.6	28	4 by 7	0.46	$16.00
500	10.0	50	7 by 7¼	2.0	28.00
1,000	10.0	100	10 by 10	1.5	56.00
1,500	10.0	150	12 by 12½	1.1	85.00
2,000	10.0	200	14 by 14¼	0.9	115.00
5,000	10.0	500	20 by 25	0.6	280.00
10,000	10.0	1000	30 by 33	0.3	500.00

Canals. — In ordinary earth a velocity too small to produce erosion and yet sufficiently great to prevent undue deposit of silt and other matter, and sufficiently great to prevent growth of weeds, should be used. For preliminary calculations a velocity of 2 ft. per second will give approximate results. For this velocity the following approximate figures will serve:

DATA ON AND COST OF CANALS IN ORDINARY EARTH

Cubic feet per second	Velocity in feet per second, V	Area of wet section, sq. ft.	Water depth, feet	Approximate slope in feet per mile	Approximate cost per running foot	
					Low	High
50	2	25	2.5	4	$0.375	$0.75
100	2	50	3.5	2	0.75	1.50
200	2	100	5	1½	1.50	3.00
300	2	150	6	1	2.25	4.50
400	2	200	7	¾	3.00	6.00
500	2	250	7	¾	3.75	7.50
1000	2	500	10	½	7.50	15.00
1500	2	750	12	½	11.25	22.50
2000	2	1000	12	⅛	15.00	30.00
3000	2	1500	15	¼	22.50	45.00

In rock the velocity in a canal may be much higher, and if the canal be lined 8 ft. per second may be used. For preliminary calculations this velocity will give approximate results. The following approximate figures are on this basis:

DATA ON AND COST OF CANALS IN ROCKS

Cubic feet per second	Velocity in feet per second, V	Area of wet section, sq. ft.	Water depth, feet	Approximate slope in feet per mile	Approximate cost per running foot	
					Low	High
50	8	6.25	2.5	40	$0.32	$1.28
100	8	12.5	3.5	25	0.63	2.50
200	8	25.0	5.0	16	1.25	5.00
300	8	37.5	6.0	12	1.87	7.50
400	8	50.0	7.0	10	2.50	10.00
500	8	62.5	7.0	9	3.25	13.00
1000	8	125.0	10.0	6	6.00	24.00
1500	8	175.0	12.0	4½	8.75	35.00
2000	8	250.0	12.0	3½	12.50	50.00
3000	8	375.0	15.0	3	18.75	75.00

Values are given for lined canals only, since a higher velocity will be allowable without producing too great a lost head and the cost will probably be more favorable.

It must be considered that these figures are wholly approximate since even for a desired useful section the amount of excavation per lineal foot of canal must vary with the character of the route — whether this be flat, rolling or side-hill.

In this connection the following approximate costs based on the annual reports of the United States Reclamation Service are of interest.

APPROXIMATE COST OF EXCAVATION PER CUBIC YARD

Class	Cost per cubic yard		
	Low	High	Fair value
1. Plowable with 4 horses	$0.098	$1.00	$0.18
1a. Plowable with 6 horses	0.1225	2.00	0.30
2. Indurated material	0.29	2.00	0.60
3. Loose Rock	0.35	3.00	0.75
4. Solid Rock	0.60	5.00	2.00
4a. Excavation below plane of saturation	0.20	3.00	1.80
4b. Solid rock under water	....	....	4.50

Tail Race. — Frequently the cost of the tail race is negligible, but for some developments the cost is an appreciable percentage of the total. No data are given for estimating tail race since those given for canals, pipes and tunnels can be used.

Receivers.— No data are given for approximation of the costs of reservoirs, vent-pipes and surge tanks on account of the varied character of these. Generally speaking the percentage of the total hydro-electric cost to be allowed for these is small and a lump sum or a percentage can be allowed for the same.

Hydroelectric Power Houses. — The following figures upon the approximate space and cost of hydroelectric power houses are wholly approximate, and will give only a rough idea of what may be expected under ordinary conditions, without any allowances for high freight, long haulage, unusually expensive labor charges, etc.; and a wide departure from these figures is to be expected. See also the articles on *Water Wheels, Generators, Transformers, Switchgear, etc.*

DIMENSIONS AND COST OF POWER HOUSES

Item	Low head*			Medium head*			High head*		
	Small†	Medium†	Large†	Small†	Medium†	Large†	Small†	Medium†	Large†
Cu. ft. per kw. for hydraulic apparatus	30	20	10	7	6	5	6	5	4
Cu. ft. per kw. for generators, exciters and switchboards (no transformers)	20	18	15	18	13	10	16	12	10
Cu. ft. per kw. for generators, exciters, transformers and switchboards	30	25	20	28	20	15	26	19	15
Total cu. ft. per kw. for hydroelectric power house (without transformers)	50	38	25	25	19	15	22	17	14
Total cu. ft. per kw. for hydroelectric power house (with transformers)	60	45	30	35	26	20	32	24	19
Approx. cost of power-house building not including foundations (without transformers) per kw:									
Low	$5.00	$3.80	$2.50	$2.50	$1.90	$1.50	$2.20	$1.70	$1.40
High	15.00	11.40	7.50	7.50	5.70	4.50	6.60	5.10	4.20
Approx. cost of power-house building, not including foundations (with transformers) per kw.:									
Low	$6.00	$4.50	$3.00	$3.50	$2.60	$2.00	$3.20	$2.40	$1.90
High	18.00	13.50	9.00	10.50	7.80	6.00	9.60	7.20	5.70
Approx. cost per kw. for hydraulic machinery	15.00	12.00	7.00	12.00	10.00	7.00	10.00	8.00	5.00
Approx. cost per kw. for exciters, generators, switchboards and cables (without transformers)	24.00	15.00	10.00	20.00	12.00	9.50	15.00	9.50	7.50
Approx. cost per kw. for exciters, generators, switchboards, transformers and cables	32.00	22.00	16.00	27.00	17.00	14.00	22.00	14.00	12.00
Approx. cost per kw. for complete power-house and foundations (without transformers)	54.00	38.40	24.50	39.50	27.70	21.00	31.60	22.60	16.70
Approx. cost per kw. for complete power-house and foundations (with transformers)	65.00	47.50	32.00	49.50	34.80	27.00	41.60	29.20	22.70

* Low head = 50 to 200 ft.
Medium head = 200 to 600 ft.
High head = 600 and above.

† Small capacity = 200 to 1000 kw.
Medium capacity = 1000 to 5000 kw.
Large capacity = 5000 kw. and above

It is assumed that the large capacity stations with transformers will be for a line voltage of from 60,000 to 110,000, the medium from 40,000 to 60,000 and the small from 10,000 to 40,000.

Overhead and Organization Expenses. — In addition to the expenditures for the actual construction of the physical plant allowance must be made for the following items to cover overhead and organization expenses.

Engineering and Contingencies. — This item should cover all the cost of engineering, drafting and supervision of construction and of all the items properly chargeable to construction engineering; 5 per cent of the construction cost is a conservative estimate for this item. An equal amount (5%) is also generally allowed to cover contingencies, errors, etc.

Administration. — All items which go to make up the cost of administration for construction, general office expense, etc., come under this head. An additional charge of 5 per cent of the construction cost should also be ample to cover these expenses.

Organization. — This item covers the cost of organization and promotion, such as legal expenses, allowance for brokerage connected with the disposal of the securities, discount on the same, etc., 5 to 10 per cent of the construction cost is usually allowed for this item.

Taxes and Insurance. — Taxes must be provided for until the operation is begun, and usually for some time thereafter, until the income is available for such expenses. Similarly with insurance, including fire, casualty, etc. One per cent of the construction cost is generally allowed to cover these items.

Interest During Construction. — Allowance must also be made for the accrued interest on the idle capital during the construction period.

Working Capital. — A certain amount of money should be provided for working capital, the amount depending on the nature of the business transactions. About 1 per cent of the construction may be allowed to cover this item.

OPERATING COST AND FIXED CHARGES. — (*See also section below on Capital and Annual Costs of Some Typical Plants.*) The cost of hydroelectric power can be considered as made up of two parts: the operating expenses and the fixed charges. The former consist of: (1) Labor; (2) Administration; (3) Oil, Waste, etc.; (4) Maintenance and Repairs; and the fixed charges of: (5) Interest; (6) Depreciation; (7) Taxes and Insurance.

It is difficult to give any general figures as to the cost of generating hydroelectric power, on account of the widely varying cost of such developments. The load factor also has a very great bearing on the cost, much more so than with steam plants because the items making up the power cost are affected very little by a change in the load.

The annual operating cost per kilowatt of generator capacity in general (excluding transmission costs) ranges between the following values:

Labor	\$1.00 to \$2.00
Administration	0.25 to 0.50
Oil, Waste, etc.	0.25 to 0.50
Maintenance & Repairs	1.00 to 2.00
Total operation	\$2.50 to \$5.00

Or, considering the annual cost items as percentage of the capital cost, the following figures are representative for a large station for which the capital cost is \$125 per kilowatt, transmission costs excluded:

	Per cent
Labor	1.00
Administration	0.25
Oil, Waste, etc.	0.25
Maintenance & Repairs	1.00
Taxes & Insurance	1.00
Depreciation	3.50
Total	7.00

The cost of power per kilowatt is thus 7 per cent of \$125 or \$8.75. Power at the bus bars of such a station could then be sold for \$16, say, per kilowatt-year, leaving \$7.25, or approximately 6 per cent for interest on the investment.

Primary and Secondary Power. — Hydroelectric power is generally sold as primary and secondary power. The former must be supplied continuously and is usually marketed by the horse-power-year or kilowatt-year. The secondary power is only available during certain months of the year, and the price obtained for it is necessarily considerably less than for the primary power. To maintain the primary power at the most economical value a steam auxiliary station is usually required; this is frequently obtained by operating the hydroelectric plant in conjunction with an existing steam plant.

CAPITAL AND ANNUAL COSTS OF SOME TYPICAL PLANTS. — Below are given data on some typical plants, ranging in size from 750 to 16,000 horse-power.

Minidoka Project. — The following data illustrate the development and power cost of the Minidoka project of the U. S. Reclamation Service:

COST OF GENERATING STATION

Capacity of station, 7000 kw.
Transmission voltage, 33,000
Hydraulic head, 46 feet

Item	Total cost	Cost per kw.
Building	\$82,000	\$11.70
Hydraulic machinery	73,000	10.40
Electric machinery	83,000	11.80
Freight and hauling	26,200	3.75
Erection	55,500	7.90
Tailrace	60,000	8.50
Roads and telephone lines	7,300	1.10
Camp and permanent quarters	23,200	3.30
Engineering and incidentals	11,100	1.55
Administration charges, etc	15,000	2.10
Total	\$436,300	\$62.30

ANNUAL COST OF OPERATION

Item	Expense per year
Operation:	
Labor	\$5,700
Supplies	950
Repairs:	
Labor	900
Supplies and material	300
Superintendence, clerical, camp, etc	1,700
General expense and administration	450
Operating expense	\$10,000

A depreciation of 5 per cent ($21,800) has also been charged to this development. No taxes or interest is charged, the undertaking being done by the Government. Assuming 7 per cent for interest and taxes the total operating expenses would amount to $62,000. A total of about 15 million kw-hr. were delivered during the year, thus corresponding to a cost of $0.0041 per kw-hr.

Costs Reported by Ontario Commission. — The following table gives the estimated cost of development and yearly operating expenses of various plants from reports of the Ontario Hydro-Electric Power Commission.*

Location of development	Available head in feet	Developed power in horse-power	Estimated capital cost	Cost per horse-power	Annual operating expenses, including administration	Annual maintenance and repairs	Depreciation	Interest at 4 per cent	Total annual charges
			$	$	$	$	$	$	$

(*a*) Expensive dam.
(*b*) Inexpensive construction of canal and headworks.
(*c*) Includes storage development.

* Capital costs cover hydraulic development (such as dams, headworks, pipe lines), power house, hydraulic and electrical equipment, with one spare unit, and step-up transformer station with electrical equipment. It does not include cost of vested rights and land damages or transmission lines.

BIBLIOGRAPHY. — Below are given references to some of the more important hydroelectric stations. A great amount of valuable data on the control and transmission of energy from hydroelectric stations is also given in the report of the Engineering Data Committee of the A.I.E.E., entitled *Engineering Data Relating to High Tension Transmission Systems* presented at the annual convention of the A.I.E.E., June 25, 1914.

[D. B. Rushmore, assisted by E. A. Lof.]

POWER STATIONS, STEAM-ELECTRIC. — (*See also Power Stations, Gas-electric; Power Stations, Hydroelectric; Boilers; Condensers; Generators; Steam Engines; Steam Turbines; etc.*) The following is a brief table of contents of this article:

LOCATION. — The selection of a site for a power plant depends on the following factors:

(1) The cost and availability of land, adequate in area and suitable in form for present and future needs.

(2) Provision for the economical handling of fuel and ashes. The site should afford navigable water frontage if possible and railroad connection in every case unless the delivery of coal by water is assured at all seasons. In comparing sites the cost of dredging channels and of track construction, including right of way, should be carefully considered.

(3) The nature of the water supply. Ample water supply from natural sources suited to all the needs of the plant is highly desirable. The life, efficiency and cost of maintenance of boilers and condensers depend greatly on the quality of the water supply. Water analyses should be made in connection with preliminary surveys.

(4) The bearing power of the sub-soil for foundations, the probability of costly difficulties in construction, the elevation of ground water, the normal, maximum and minimum stages of adjacent bodies of water.

(5) The general character of the surroundings and the existence of restrictive ordinances relating to smoke, noise, vibration and the movement of coal cars.

(6) Proximity to the load center of gravity, if power is to be distributed at low voltages.

FOUNDATIONS. — (*See also Concrete; Concrete, Reinforced.*) The design of foundations depends on the bearing power of the soil, the concentration of loads and the necessity of suppressing vibration. For table of the bearing power of various soils see the article on *Power Stations, Hydroelectric*.

The taking of borings is usually essential to the proper design of foundations, especially where the site is on alluvial soil near a water frontage. Concentrated loads may reach a maximum of 15 tons per square foot. Foundation footings should rest on rock whenever practicable. Soils of inadequate bearing power are reinforced by driving piles of wood or concrete at points of concentrated load or under the entire foundation, as the soil may require. Rafts of reinforced concrete resting on a soil stratum or on piling are often used to distribute loads, to prevent the flowage of alluvial soil and to reduce the transmission of vibration. The foundation structures proper are usually of reinforced concrete. The following table of safe loads on foundations is given in Snell's *Power House Design*.

Foundations for machinery are usually made separate from those of the walls to reduce the transmission of vibration. Boiler-room equipment is usually carried on the steel framing of the superstructure, but main generating units have separate foundation piers of concrete. Foundations for reciprocating engines have extended bases, and in extreme cases cushions of felt, sand or rubber composition are provided to suppress vibration. Anchor bolts for machinery are

TABLE I. — SAFE LOADS ON FOUNDATIONS

Loads in tons per square foot

Good concrete	4
Steel rails in concrete	8
Concrete piles	12
Ordinary bricks in cement mortar	5
Hard bricks in cement mortar	8
Blue bricks in cement mortar	12

accurately located in concrete work by means of templates. Bolts may be cast in the foundations, or holes may be provided, together with side holes to permit the adjustment of the bolts. When the concrete has set, the machine is lifted into place, aligned and leveled and the interstices run in with cement grout.

The datum line of a power plant should be fixed by consideration of water levels. Tidal limits and flood water stages fix the levels of condenser intake and outlet tunnels, of engine room floors and of furnace grates.

SUPERSTRUCTURE. — A power house should be fireproof in every respect, clean, well-lighted, well-ventilated and well-drained. The skeleton structure is usually of steel with wall panels of brick or of reinforced concrete. All structural members should be computed with a factor of safety of not less than 3 (*see Structures, Simple*). The most heavily-loaded members are the pillars carrying overhead bunkers and those supporting an engine-room crane. The roof should be of fire-proof material, truss-supported and with sufficient pitch to insure good drainage. The roof may properly have glazed monitors to assist in lighting and ventilation. Windows in the generating room and switch houses should be designed to exclude rain when partly open.

Interior walls are usually finished in brick set with close joints and neatly pointed. Glazed brick or tile are appropriately used for walls in generating rooms. The upper portion of such walls should be of light color. The basement floors are usually of smooth cement. Generating room floors should be of tile, brick or other material not tending to form dust. The boiler room floors are usually hard-burned brick or special concrete. The battery rooms should have floors of brick or acid-resisting asphalt. Stairways are preferably of iron and should be provided with non-slip treads.

Recent practice has evolved a standard type of building division, providing a boiler room and a generating room side by side and separated by a solid wall. All electrical control apparatus is placed at the side of the generating room opposite the boiler room on galleries outside the crane span or in a separate section of building. This general ground plan has a number of important advantages. The framing may be proportioned to the loads in the different sections, the boiler plant and generating plant may be extended with equal facility, all wiring is isolated from steam piping, dirt and smoke are excluded from the generating room and accidents may be isolated in the section in which they arise.

BOILER-ROOM LAYOUT. — (*See also Boilers; Chimneys; Draft, Mechanical; Fuel; Smoke Prevention; Steam; Stokers, Mechanical; Feed-water Heaters and Purifiers.*)

Capacity and Number of Boilers. — The rating of boilers is purely nominal and their evaporative capacity is limited largely by the rate at which fuel can be economically burned in their furnaces. A well-designed unit is capable of giving from 75 to 100 pounds of equivalent evaporation per hour per rated horsepower, though forcing to this extent involves some sacrifice of efficiency. The

boiler plant should have sufficient steaming capacity to operate all steam machinery at its maximum output during the period of peak load, plus reserve capacity to insure against boiler shut-downs. The most economical boiler capacity depends largely on the form of the load curve. It is economical to force boilers to very high outputs during short and severe peaks, due to the reduction of investment and of fuel required for banking fires. With a very even load curve lacking extended banking periods it is most economical to install capacity sufficient to carry the average load at the highest efficiency. In modern public service stations it is customary to draw on boilers up to 200 or 250 per cent of their nominal ratings during peak loads. In a large number of modern stations ranging in capacity from 400 to 10,000 kw. the average boiler installation was found to be 0.4 boiler horse-power per kilowatt of generating capacity. In very large stations of recent design this ratio is from 0.25 to 0.3 boiler horse-power per kilowatt.

The simplest arrangement possible is to group with each generating unit one or two boilers, but this scheme lacks operating flexibility. In large steam plants the boilers are all operated in parallel on a common steam header, though provision is often made to isolate groups of boilers in emergencies. With this arrangement the boiler plant may properly be subdivided into the number of units affording the greatest economy and convenience. Large boilers are usually more efficient than small. The unit costs of boilers, stokers, piping, flues, air ducts and building are apt to be less for large boilers than for small. The crippling of a large boiler withdraws from service a larger portion of the total capacity and correspondingly larger reserve equipment may be needed. There is no evidence to show that small boilers afford greater safety than large. In general a boiler plant should comprise not less than 4 units if continuous operation is anticipated.

Grouping of Boilers. — Two common boiler room plans exist. In one the boilers are ranged in a single or double row facing a firing aisle which runs the length of the plant. In the other there are several lateral firing aisles, each serving a double row of boilers. The former plan is appropriate when the aggregate length of firing aisle does not exceed the length of the generating room. The latter plan lends itself well to the unit or group scheme of connection to generators. When the greatest economy of ground space is necessary, the boiler plant is double-decked, but this plan complicates the handling of fuel and ashes, reduces the natural light and ventilation and requires a building of very heavy framing. A basement space is provided below the boiler room. This space contains the ash hoppers, air ducts for forced draft and ash disposal equipment. Boiler feed pumps, blowers, hotwells, feed water heaters and flues are often placed in this space. The head room of the basement should be not less than 10 feet.

Boiler Spacing and Clearances. — With few exceptions boilers are set in batteries of two, with a space of 5 feet or more between batteries. A space not less than 5 feet wide should be left behind the settings for repair work, access to blow-off valves and minor piping. If the main piping or flues occupy this space it should be at least 8 feet wide. Each firing aisle should afford ample space to withdraw boiler tubes, drums and furnace structures for replacement or repairs. The width is usually between 18 and 25 feet and varies with the type of boiler and furnace. Clear head room above the boilers should be ample to install and repair the main piping and valves and to remove and replace boiler drums. An allowance of from 10 to 12 feet is usually ample. The following table gives minimum allowances of floor space for water-tube boilers of the most widely-used types, set in batteries of two:

TABLE II. — MINIMUM BOILER ROOM SPACE ALLOWANCES FOR WATER-TUBE BOILERS

400-hp. units in batteries of two...........	1.25 sq. ft. per hp.
500-hp. units in batteries of two...........	1.20 sq. ft. per hp.
600-hp. units in batteries of two...........	1.05 sq. ft. per hp.

In power plants of modern design the actual boiler room area per boiler horse power ranges from 0.9 to 2.00 square feet, the average being very nearly 1.4 square feet.

Location of Flues. — Boiler flues may be placed on the floor at the rear of the settings, in the basement space beneath the rear of the boilers, or may be carried overhead. Flues may be of brickwork or of steel plates reinforced with angle-iron stiffeners. In the most compact designs steel flues are used over the rear of the settings. Brick flues should be lined with firebrick. Steel flues are built up from 1/8-inch plates when indoors and of 3/16-inch plates outdoors. Flues should be as short, air-tight and straight as possible and should preferably have an upward gradient toward the chimney. It is good practice to allow from 4.5 to 5.5 square feet of flue section for each 1000 pounds of coal burned per hour in the boilers served. Branch flues should be equipped with swivel dampers to permit boilers to be shut down independently.

Location of Economizers. — Economizers are most frequently set on a steel gallery above the rear of the boiler setting. Less frequently they are set on the boiler room floor behind the boiler settings or on a floor above the boiler room. Each economizer unit is provided with a by-pass flue below or behind the economizer setting. A soot chamber is provided beneath the tubes and should be from 2 to 2.5 feet in depth. Access must be allowed along the front of the economizer to permit the opening of the cleaning holes in the bottom branch pipes. Clear space of 10 feet or more is required above the setting to permit the withdrawal and replacement of the tubes. Economizers are usually set in brickwork and subdivided into sections, each associated with a battery of boilers. A large central economizer can often be installed at lower cost, but affords less flexibility in operation.

Chimneys and Mechanical Draft Appliances. — *(See also Chimneys; Brick and Brick Masonry; Draft, Mechanical.)* Brick chimneys are usually carried down to foundations independent of the building and outside of its walls. In exceptional cases where greatest space economy is necessary, brick chimneys are carried by steel columns integral with the framing of the boiler house. Steel stacks are usually supported on cast-iron base plates carried by the structural frame work of the boiler house. Fans for forced draft are commonly set at centrally located points on the boiler room floor and distribute air to the various furnaces through ducts of sheet steel beneath the main floor. Induced draft fans are usually installed in duplicate and are located at the bases of the chimneys. Short steel chimneys are generally employed with induced draft systems.

Coal and Ash Handling Equipment. — *(See also Conveyors; Cranes; Fuel; Hoists, Electric; and Unloaders.)*

Coal Storage, External. — Continuity of fuel supply is a vital necessity to power stations. Insurance against interruptions of delivery is commonly made by use of internal bunkers and external coal storage yards. The amount of fuel to be kept in reserve is a local problem and depends on the certainty of delivery, the fluctuation of the market, the rate of deterioration of coal in storage and the danger of spontaneous combustion. Coal exposed to the weather loses heat value at a rate which depends on its content of volatile fuel and which may

exceed 1 per cent per month. Coal stored in deep piles is liable to spontaneous ignition, especially if it contains much sulphur. Both difficulties may be obviated by storing coal in basins under water. Bituminous coal should not be piled deeper than 35 feet unless submerged. As a precautionary measure iron pipes may be sunk into coal piles at intervals and the temperature read periodically by a suspended thermometer. A coal yard is commonly spanned by a gantry crane carrying an automatic grab bucket for distributing and reclaiming.

Coal Storage, Internal. — Internal storage is provided in overhead bunkers supported by the boiler house framing above the firing aisles. Bunkers are of two general types, suspended steel tanks hung from the framing, and hopper-shaped structures of reinforced concrete incorporated into the building proper. Suspended bunkers are usually concrete-lined and have a limited storage capacity, the practicable limit being about 10 tons per linear foot. Built-in bunkers are best adapted to large storage capacities up to 40 tons per linear foot. Bunkers should be divided by transverse bulkheads to increase their strength and assist in isolating trouble from spontaneous combustion. Hopper bottoms should have a slope of 45° or more to make them self-clearing. Cut-off gates should be provided at point of attachment to down-spouts. Automatic weighing and recording hoppers may be installed between bunkers and down-spouts to good advantage as their records assist in keeping check on boiler performances. Down-spouts should be not less than 12 inches in diameter and should be slightly inclined to lessen the tendency of the coal to pack. The firing aisle is sometimes equipped with an electrically-operated traveling hopper which may draw coal from any desired bunker section and distribute it to the several stokers.

The bunker capacity desirable in a boiler plant depends on the extent of the external storage and the facilities for fuel handling. Bunker capacity sufficient for from 4 days' to 7 days' supply is generally adequate. Very large bunkers are costly and are apt to lead to trouble from spontaneous ignition. In computing bunker capacity it is customary to allow 40 cubic feet per ton of coal.

Coal Handling. — The handling of coal which is delivered by rail and is to be delivered directly to overhead bunkers is most readily accomplished by the following plan. The loaded car is run over a track hopper into which it dumps from beneath. The hopper delivers to a crusher which reduces the coal to a uniform size suitable for the use of the stokers. The coal is delivered by the crusher to an elevator which may consist of some type of skip hoist, inclined belt or endless chain of buckets. If a skip hoist or belt is used the coal is dumped into a receiving hopper after its ascent and is finally distributed to the bunker by a horizontal belt, flight or bucket conveyor. A chain of pivoted buckets may be used as both elevator and distributor.

When the boiler room is arranged on the unit plan, i.e., boilers in rows facing transverse firing aisles, each aisle should have its bunker system, track hopper, crusher, elevator and conveyor. Such a conveyor may properly be of the pivoted-bucket type and may serve to elevate and distribute coal or to collect ashes from the ash hoppers beneath the boilers and deliver them to an ash bunker built out over the railroad track.

Reliability is a most important factor in all coal-handling systems and is promoted by making the system mechanically simple and rugged, by installing duplicate sets of equipment and by the sectionalizing of bunkers and conveyor outfits into independent units.

Coal delivered by water is usually handled by a clam-shell or grab-bucket unloader which dumps it into a receiving hopper. After being crushed the coal is conveyed to the storage yard or bunkers by equipment similar to that just described.

Ash Handling. — If ashes are handled by a conveyor when wet or hot the corrosive action on the buckets may make maintenance costly. When the ashes are not handled by a conveyor system it is customary to provide a track running beneath the ash hoppers on which small cars may be run to haul ashes to the dump.

Feed-water Systems. — (*See also Pipes and Piping; Feed-water Heaters and Purifiers; Pumps and Pumping Engines; and Valves.*) Condensing plants usually draw feed water from the hot-wells of the condenser system. When surface condensers are used a small amount of make-up water must be added from outside sources. The water discharged from jet condensers may be used for boiler feeding if of suitable quality. Non-condensing plants operating in connection with steam heating systems usually draw feed water from the return system, with added make-up water as required. Open heaters of all types are placed on the suction side of feed pumps. Closed heaters are placed on the delivery side. Meters are usually placed in the delivery pipe and should be in duplicate if continuous indication is important. Otherwise they should be by-passed, as are all heaters and economizers, to provide for cleaning and repairs during operation.

Water is supplied to boilers through a feed main which is run along the front or rear of the boilers, often in the basement space below. Double and ring mains are occasionally used though the gain in reliability is doubtful. An auxiliary injector main running direct to boilers from the source of cold water is sometimes installed as a reserve. Iron pipe is generally employed with cold water and brass pipe for water above 200° F., or water which has a pitting tendency. Screwed joints are generally used with pipe diameters less than 2 inches. Larger pipes are fitted with screwed flanges.

Feed pumps should be installed in duplicate on each feed main or cross-overs provided between pumps. There is wide divergence in the location of feed pumps. In most plants of the unit type each feed pump is associated with the auxiliaries of a generating unit and is cared for by the turbine operator or oiler. In other cases feed pumps are grouped in a central position on the main floor of the boiler room and are cared for by a water tender. In other cases the feed pumps are placed in a separate basement pump room.

A relief valve should be placed in the pump delivery to prevent strains from excess pressure. The size of feed pipe is usually such as to allow a maximum velocity of from 300 feet to 400 feet per minute. At least two valves, a regulating valve and a check valve, should be placed in each boiler branch.

Condenser Water System. — (*See also Condensers, Steam; Cooling Systems for Power Stations.*) Cooling water for condensers is obtained from an adjacent body of water whenever possible and in other cases from a cooling pond or the basin beneath a cooling tower. In the former case large concrete intake and discharge tunnels are usually provided. These run beneath the generating room in alignment with the intake and discharge pipes of the condensers. The cross-section of these tunnels should be ample to keep the flow of water down to 5 or 6 feet per second. Intakes should have generous openings fitted with trash racks and should if possible be placed at a considerable distance upstream from the discharge outlet. In some cases it is necessary to build a baffle wall in the stream between the two tunnels. A shut-off gate is usually provided in each tunnel to facilitate cleaning and repairs. The tunnels should be of sufficient depth to insure an adequate supply of water at the lowest stage of tide or stream flow. The circulating system of surface condensers is fully enclosed and the work done by the circulating pump is merely that necessary to overcome the fluid friction in the system.

GENERATING ROOM LAY-OUT. — (*See also Condensers, Steam; Cranes; Feed-water Heaters and Purifiers; Generators, Alternating Current; Generators, Direct Current; Lubricants and Lubrication; Pipes and Piping; Pumps and Pumping Engines; Steam Engines; Steam Turbines; and Valves.*)

Capacity and Number of Units. — A generating plant should have sufficient capacity to serve its peak load with any one generating unit shut down. The reserve capacity needed above normal requirements may be provided most economically by selecting types of equipment capable of giving large overloads in emergencies, by maintaining in service condition obsolete machinery which is physically sound but uneconomical, by installing a large reserve storage battery, or by tying in parallel several power plants so that a moderate reserve may be shared in common. More reserve capacity is needed when a plant contains few large units than with many of small size. A smaller number of units than four is disadvantageous, due to the relatively large reduction of capacity by the disabling of one. A larger number than eight units has no inherent advantages. Large units are generally more economical than small units if kept well loaded. If the plant has a normal daily period of very light load it may be economical to employ one small unit well suited to this load.

Types of Equipment. — Steam-turbine generators are now almost exclusively for alternating-current generation in units exceeding 500 kw. The turbine has little or no advantage over the engine in smaller sizes and in non-condensing plants the engine is often superior. On account of its high speed the turbine is poorly adapted to the direct driving of d-c. generators. Large d-c. generators are becoming obsolete in steam plants, for it is usually more economical to generate alternating current in turbine units and convert it to direct current either locally or in distant substations. A self-contained unit comprising boiler, engine and condenser, known as the *locomobile*, has been largely used in very small European plants and is now being introduced in America.

Arrangement of Generating Rooms. — The modern standard power house has a long and narrow generating room placed between a boiler house and a switch house or series of electrical control galleries. The generating room is spanned by an electrically-operated crane. The generating units are usually ranged along this room in a single or double row. Each unit comprises a prime mover, electric generator, condenser and the associated pumps and their motive power. In most instances a basement space or series of open pits is provided below the main floor in which the condensers, pumps and most of the piping are located.

Arrangement of Turbines. — In many plants using vertical-shaft turbines the basement has been omitted and the auxiliaries grouped about the base of the turbine on the main floor. In such cases the condenser is either incorporated into the base of the turbine or is placed on the floor immediately beside it. This grouping of equipment on a single floor has several operating advantages. All apparatus has good light. A single operator can give efficient attention to a large group of equipment, and machinery so placed usually receives closer attention than it would in a pit or basement. All pieces can be readily handled by the crane without interference with other apparatus. The ample head room is advantageous in making repairs. The basement plan is especially economical of floor space, but makes the auxiliaries relatively less accessible. Placing condensing equipment in open pits beside the engine or turbine piers makes it accessible for inspection and for handling by the crane.

In determining the arrangement of a generating room it is essential to provide each element with ample space for all needed attention during operation or repairs. Sufficient clear floor space about a unit is usually provided to permit it to be dismantled without removing the parts to a distance. Clear trucking

space is also desirable. The separate pieces of machinery should be so arranged that the crane can be conveniently used in assembling or dismantling any piece without interference with others. Clear overhead space below the crane hook should be sufficient to permit any heavy part to be lifted clear of its setting and carried away. The crane girder and trolley must clear all roof trusses and lighting fixtures. Clearance must be allowed at the generator ends of horizontal turbine units to withdraw the revolving field structures.

Arrangement of Condensers. — In setting surface condensers clear working space must be allowed at both ends to remove the heads and at one end clear space must be allowed to permit the withdrawal and replacement of tubes. Jet condensers should be set in such a manner that the head can be conveniently opened for repairs. Condensers in general should be set below the level of the associated prime mover and as close as possible to its exhaust port. The condenser connection should provide natural drainage for condensed steam. It should have as few joints as practicable to avoid occasion for air leaks. It is usually desirable to provide a copper expansion section in this connection as joints in a rigid pipe are difficult to keep air-tight with varying temperatures. The arrangement of a central condenser serving a group of prime movers is uncommon in electric power plants. Barometric jet condensers are often placed outside of the wall of the building on account of the long tail pipe required.

Floor Space in Generating Rooms. — The floor space provided per kilowatt varies greatly with the size, type and arrangement of equipment. The following data from modern steam-turbine stations are illustrative of the range of best practice.

TABLE III. — SPACE COVERED BY STEAM-TURBINE POWER STATIONS

Station No.	Capacity, kilowatts	Boiler room, square feet per kilowatt	Turbine room square feet per kilowatt	Total, square feet per kilowatt
1	3,000	0.71	0.70	1.41
2	8,000	0.74	0.69	1.43
3	11,000	1.11	0.70	1.81
4	13,500	1.13	0.50	1.63
5	16,000	0.90	0.37	1.27
6	24,000	0.92	0.40	1.32
7	30,000	0.44	0.40	0.84
8	32,000	0.60	0.30	0.90
9	100,000	0.48	0.17	0.65

Oiling Systems. — (*See also Lubricants and Lubrication.*) Steam power plants afford three classes of lubrication problems, viz., wearing surfaces exposed to high temperature steam, as in cylinders, valve chests and stuffing boxes; atmospheric surfaces of open guides and journals; and enclosed surfaces, chiefly journals. Steam surfaces are lubricated with cylinder oils of mineral origin supplied in atomized form by forcing the oil in small quantities into the steam supply pipe. Oil may be supplied by a local force-feed pump or hydrostatic lubricator or may be supplied from a central tank and pump supplying a group of cylinders. Bearings, guides and other exposed surfaces are lubricated by oil or grease supplied by hand or from adjustable feed cups. Enclosed surfaces are usually lubricated by splashing or by flooding with oil from a central source of supply. The flooding system is most efficient. Oil from a central tank is

forced by pump or gravity to the various working parts whence it returns through a drip system to collecting pans and filters. After purification a small amount of make-up oil is added and the reclaimed supply restored to the oiling system.

PIPING SYSTEMS. — (*See also Pipes and Piping; and Valves.*) The various piping systems in a power plant are subdivisible into the following groups: (*a*) High-pressure steam piping between boilers, main units and auxiliary engines; (*b*) exhaust piping to condensers; (*c*) exhaust piping to feed-water heaters; (*d*) atmospheric-exhaust piping; (*e*) feed-water piping; (*f*) cooling-water piping; (*g*) pipe-drainage system and (*h*) oil piping. To facilitate the identification of pipes of various classes it is desirable to paint each a distinctive color.

High-pressure Steam Piping. — The chief considerations in laying out high-pressure piping are (*a*) to produce a reliable system without complexity; (*b*) to make all joints permanently steam tight; (*c*) to take up all expansion strains; (*d*) to maintain proper steam pressure at all points of delivery; (*e*) to reduce to an economic minimum the loss of heat by radiation and (*f*) to drain from the entire system all water of condensation. In many older systems of piping elaborate ring and multiple headers, with numerous by-passes, cross-overs and duplicate-connection branches were employed in the endeavor to promote reliability by making possible the isolation of any fault. Reliability is sought in modern systems by very simple connections with skillful design and the best possible construction.

Unit and Parallel Systems of High-pressure Piping. — The ***unit system*** and the ***parallel system*** of connection with their various modifications are now most extensively used. The unit system of piping connects a separate group of boilers to each prime mover and its auxiliaries. The parallel system provides a large steam header running the length of the plant into which all boiler branches deliver and from which all prime movers are supplied. Unit systems are usually provided with cross-overs between unit steam and water headers to permit the parallel operation of different sections in emergencies. Parallel systems are often provided with sectionalizing valves to permit the isolation of any section in case of accident. Diagrammatic sketches of unit and parallel grouping are shown in Figs. 1 and 2.

Size of Piping. — Pipe sizes for high-pressure work are generally determined by the maximum allowable steam velocity. It has been found satisfactory and economical to allow a maximum velocity of 6000 feet per minute with saturated steam and from 9000 to 12,000 feet per minute with superheated steam. The flow to piston engines is intermittent and the pipe size should be proportioned according to the velocity during admission unless a receiver is installed. The steam header of a parallel system serves as a reservoir to equalize pressures and prevent vibrations in the piping. Its cross section is properly proportioned according to the maximum cross flow of steam with any boiler section inoperative.

Joints. — Joints in high-pressure piping are usually of the screwed type for diameters under 3 inches and of the flanged type for larger sizes. Flanged joints may be made between ground faces or by aid of gaskets, the former type being preferable for high-pressure steam. An excellent joint is made by drawing up with loose collar flanges the turned-over ends of pipe sections with faces ground true, often called a Van Stone joint. Such joints are more expensive than rigid flanged joints but the possible swing of the pipe about its axis is a great advantage in the final aligning and connecting up of a system with many branches.

Provisions for Expansion. — Provision for the expansion of pipe without straining joints and fittings is imperative. Between two points which must be rigidly fastened expansion is taken up in expansion loops and bends. The

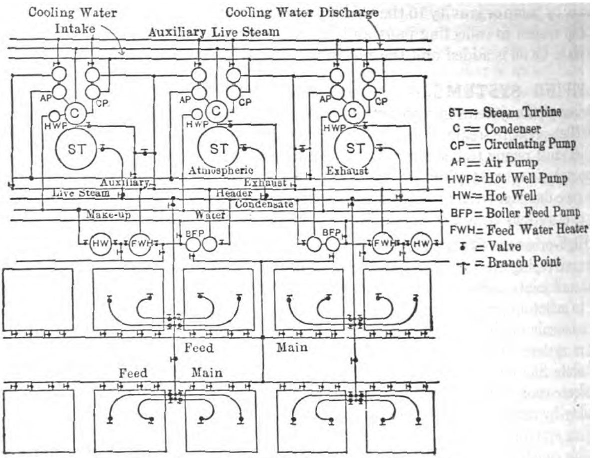

Fig. 1. Parallel Method of Connection

Fig. 2. Unit Method of Connection

radius of such bends should in all cases be not less than five times the pipe's diameter and at each end of the curve there should be a length of straight pipe not less than twice the diameter. Welded flanges are recommended for the attachment of bends. When bends cannot be used recourse must be had to swivel joints or slip joints, which should be avoided if possible. When screwed joints are employed expansion is commonly provided for by the use of sections having single, double or triple swing about a screwed connection. Pipes of considerable length must be anchored at more than one point to prevent vibration. Between each anchor expansion bends are required and the pipe must be support-

ed by hangers, roller brackets or pedestals allowing longitudinal motion. Anchorage is usually made at points of attachment to branches, and fittings with anchor bases are employed for the purpose.

Lagging. — Live-steam pipes, boiler-feed pipes, steam drums, receivers and separators should be covered with heat-insulating material to reduce the radiation losses to a minimum. The loss from bare pipe is approximately 3 B.t.u. per square foot per hour for each degree difference of temperature. Good commercial coverings, such as magnesia, felt, asbestos, mineral wool, etc., will prevent from 75 to 90 per cent of this loss if properly applied.

Drainage. — Saturated steam in passing through pipes undergoes a small amount of condensation due to friction and heat radiation. The presence of water in steam piping is a source of danger, for a water slug, if picked up by the moving column of steam, may be driven with tremendous force against any opposing surface, such as a valve, sharp bend or cylinder, with destructive results. Pipes should be slightly inclined so that water drains away from the prime movers and every point where water may collect must be provided with a drip connection. These drip connections are run through traps to the hot-well so that the hot water may be returned to the boilers. In other systems the drip water is returned directly to the boiler. Separators are often installed at the inlets to reciprocating engines and exhaust steam turbines taking wet or saturated steam, to drain the moisture from the entering steam. Drip connections should always be made to these separators. Bleeder connections to live steam lines are provided in order that the water condensed in warming up the pipe when steam is turned on may be drawn off.

Valves. —Valves for steam pipes are of two general types, gate valves and globe valves. Either type may be outside screw or inside screw, according as the screw of the spindle is outside or inside of the casting. Outside screw types are preferred for high-pressure work as the position of the spindle is then an index showing whether this valve is open or closed.

Check valves are required in boiler connections to prevent steam flowing into the boiler when cold or when its pressure is below that of the header to which it is connected. Emergency valves are often provided to cut off the steam under abnormal conditions, such as the bursting of a pipe or the racing of an engine. These often take the form of a weighted valve which closes itself when a trip is released. Electric motors and hydraulic pistons are sometimes connected to ordinary valves to provide for remote control during emergencies.

Blow-off valves of boilers are subjected to very severe service and are made exceptionally rugged. Such valves must close without leaks, open readily and furnish a free path for the ejection of scale and sediment. The wearing parts of such valves should be readily renewable. Best practice requires the use of two blow-off valves or a valve and a cock. The steam, water and sediment are usually blown through a tank partially filled with water before being exhausted to the air.

A few rules relative to the installation of high-pressure valves and piping may be noted. All valves of a diameter above 6 inches should be by-passed to facilitate opening under pressure. Valve stems are often placed horizontally to lessen the tendency to form water pockets. Angle valves should be selected whenever convenient because of the greater room in them. Branches from mains to boilers should have at least two valves, an ordinary stop valve next to the main and an automatic check valve near the boiler. Valves are best placed at the highest points in the pipe to simplify the drip system. When the flow of steam is intermittent heavy valves should not be placed far to one side of a line joining the points where the pipe is supported as they may cause vibration.

Branches from a main to a prime mover should have a stop valve at the highest point near the main. A receiver-separator from three to four times the volume of the high-pressure cylinder should be placed as close to the throttle of a piston engine as possible to equalize steam flow and drain moisture from the steam. When superheated steam is used cast-steel fittings and valves are preferred to cast iron. Branch pipes are almost invariably connected to the top of the main to prevent water from passing into the branches. When superheated steam is supplied to the main units and saturated steam to the auxiliaries a separate steam main for the latter is employed.

Exhaust Steam Piping. — The size of the exhaust pipe of a prime mover is determined by the permissible back pressure. High vacuum requires ports and exhaust piping of large diameter and the length of pipe to the condenser as short as possible. An atmospheric-relief valve which is normally closed by air pressure against a spring or weighted lever but which opens automatically when the vacuum fails should be installed in the condenser pipe. Atmospheric-exhaust pipe is usually spiral riveted as no precaution against leaks is required. This usually terminates in an enlarged exhaust head which contains baffles to drain from the steam condensed water and oil before it discharges to the air. A common exhaust main for a number of units is often employed. When exhaust steam is used for heating purposes the system is supplied through a back-pressure valve which automatically opens the atmospheric exhaust if the back pressure exceeds that required to operate the heating system and closes when normal back pressure is restored.

GENERATOR AND CONTROL EQUIPMENT. — (*See also Batteries, Storage, Applications of; Bus-Bars and Bus-bar Structures; Circuit Breakers; Generators, Alternating Current; Generators, Direct Current; Reactance Coils; Regulators; Relays; Switches; Switchboards; Switchgear Equipment for Power Stations; Transformers; Transformers, Instrument; Wires and Cables.*)

Direct-current Generators. — Three-wire lighting service may be provided (*a*) by the connection of generators in sets of two in series, (*b*) by the use of three-wire generators with external or internal compensator coils or (*c*) by the use of voltage balancer sets associated with standard two-wire generators. Railway generators are operated at or near 600 or 1200 volts and are grounded at one pole, usually the negative. Series fields and equalizer connections may be on either the positive or the negative side. Equalizer switches are often carried by pedestals near the generator terminals to save wiring to the switchboard. Satisfactory voltage regulation for railway systems is usually provided by the use of compound generators. The close voltage regulation required by lighting systems is best provided by the use of a regulator of the Tirrill type. (*See Regulators.*)

Alternating-current Generators. — Synchronous 3-phase generators are used most extensively. Induction generators are often advantageous in connection with exhaust-steam turbines. Synchronous turbo-alternators are now designed with high internal reactance to prevent excessive transient currents immediately after the creation of a short-circuit. If the internal reactance is inadequate they may be connected to the bus-bars through reactance coils. (*See Reactance Coils.*) In some cases the generators are operated at half the bus-bar voltage and are connected through raising auto-transformers wound with large reactance.

Grounding the Neutral. — Three-phase alternators are usually Y-connected and provision is frequently made for the grounding of one generator at the neutral point to prevent dangerous potential rise should a wire become accidentally grounded. More than one grounded neutral in a group of genera-

ors in parallel is undesirable, due to the possibility of a third-harmonic circulating current passing through the neutral connection.

Air Ducts for Forced Ventilation. — Modern turbo-alternators are designed for forced ventilation. A system of ducts should be provided, either overhead or beneath the floor of the generating room from which each generator may draw a supply of clean outside air. This air is forced through the ventilating spaces of the stator and rotor by the fan action of the rotor. Discharge ducts are also provided in case it is undesirable to discharge the heated air to the generating room. It is desirable to equip such ducts with dampers so that the air may be discharged indoors or outdoors as desired. In many cases where the air supply is dusty it is desirable to install air-conditioning equipment in the intake of the system. See *General Electric Review*, Vol. 16, p. 627 for a full discussion of turbo-generator ventilation.

Excitation. — Fig. 3 shows the exciter capacity required by modern alternators. In small plants each alternator is often provided with its individual exciter driven by the main shaft. Large stations are provided with central

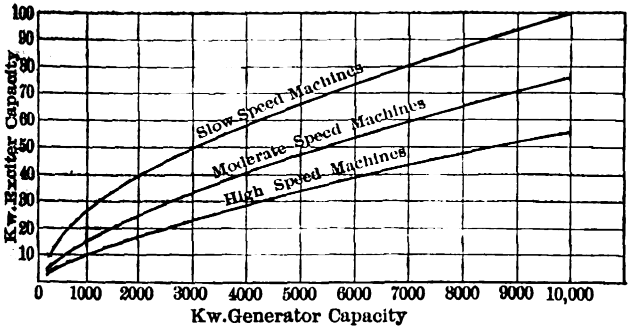

Fig. 3. Exciter Capacity Required by A-C. Generators

systems of excitation comprising not less than two, and generally more, direct-current generators, driven by independent motive power. At least one exciter in every plant should be steam-driven. Three-phase induction motors are quite generally used for the electric driving of exciters. The exciter system is frequently reinforced by a floating storage battery to insure the supply of exciting current in every emergency. (*See Batteries, Storage, Applications of.*) All alternator fields are supplied through adjustable rheostats from a set of excitation bus-bars, except that in a few very large plants the excitation system is sectionalized for the sake of reliability. Exciters are commonly rated at 125 or 250 volts, and are usually compound-wound, with magnetic circuits normally in a state of low saturation. The best position for exciters in large stations is generally near the center of the generating floor.

Voltage Control. — In both alternating- and direct-current stations very sensitive regulation of the bus-bar voltage may be obtained by the use of appropriate types of Tirrill regulators. (*See Regulators.*) When the load variations of different feeders are quite unlike it is often desirable to provide each feeder or group of parallel feeders with independent feeder regulators, which may be hand-operated or may be automatically controlled by voltage relays.

Transformers. — The arrangement of the transformers depends to some extent upon the type used. When it is not convenient or possible to allow above

each transformer clear head-room for crane handling, the transformer cells may be arranged to open at one side along a track and have raised floors at the level of a flat car, so that the assembled units may be slid into or out of place.

Air-blast Transformers. — These are largely used for step-up service in power stations in connection with feeders operating at 20,000 volts or less. Railway transmission lines and feeders operated at more than 20,000 volts are usually supplied through oil-insulated, water-cooled transformers. Air-blast transformers are usually placed above a common pressure pit whose air-supply is drawn from out-doors by electrically operated fans. Each transformer may be equipped with adjustable dampers to regulate the air supply.

Oil-insulated Transformers. — In some cases oil-insulated transformers are isolated in fire-proof cells built of concrete or masonry. The fire-risk is usually not sufficient to warrant isolation for each unit, but it is often desirable to enclose each 3-phase bank. Large oil-insulated transformers should be connected to an oil-drainage system to facilitate the withdrawal and replacement of oil.

Switching Equipment and Wiring. — For descriptions and standard arrangements see the following articles: *Bus-Bars and Bus-bar Structures; Circuit Breakers; Regulators; Relays; Switches; Switchboards; Switchgear for Power Stations; Synchroscopes; Transformers, Instrument;* and the articles on the various kinds of meters.

Wiring. — In direct-current stations the power conductors are usually rubber-insulated copper cables run from generators to switch-board and thence to outside circuits in ducts of tile or fiber. In some cases the duct system is dispensed with and the conductors are carried on open wallracks spaced by insulating knobs. In small alternating-current stations the wiring to and from the switchboard is usually in a duct system, but the switchboard and bus-bar wiring is open and is supported by porcelain insulators on walls and on a light frame work of pipes or angle-irons.

In plants of 12,000 kilowatts and up, operating at voltages of 20,000 or less, it is customary to isolate all conductors of unlike polarity as fully as possible in fireproof cells and barriers. The essential features of such a system of isolation are as follows: — (1) Each horizontal run of conductor is drawn into its individual duct of tile or fibre set in a concrete floor; (2) each bus-bar is mounted in a separate horizontal cell of concrete or masonry; (3) each instrument transformer and disconnecting switch is in a separate cell; (4) each pole of a bottom-connected oil switch or each complete top-connected switch is in its separate cell; and (5) vertical fire-proof barriers are placed between all vertical runs of conductor. Isolation of this nature is seldom practiced in systems above 30,000 volts, but open overhead wiring with generous spacing is employed.

In an enclosed system the power connections are appropriately formed by single-conductor copper cables, insulated with rubber or with cambric tape, and covered with a fire-resisting sheath. Lead sheathing is seldom employed unless the wiring is exposed to dampness. The cross section of such conductors is determined by the safe limits of temperature rise.

COST OF STEAM POWER STATIONS. — Power station costs are subject to wide variations with the type and elaborateness of equipment, construction difficulties and rated capacity.

Capital Costs. — Illustrative data showing the range of unit costs of the chief divisions of plant equipment are given by O. S. Lyford, Jr., and R. W. Stoval of the Westinghouse, Church, Kerr Co., in the Electric Journal, 1912, Vol. 9, p. 322, as follows:

TABLE IV. — COSTS OF STEAM-ELECTRIC POWER STATIONS

Capacity, 2000 to 20,000 kw., based on maximum continuous capacity of generators at 50° C. rise

Item	Dollars per kw.	
	High	Low
Preparing Site: Dismantling and removing structures, making construction roads, tracks, etc.	0.25	0.00
Yard Work: Intake and discharge flumes for condensing water, railway siding, grading, fencing, sidewalks	2.50	1.00
Foundations, including foundations for building, stacks and machinery, together with excavation, piling, waterproofing, etc.	6.00	1.00
Boiler Room Equipment, including boilers, stokers, flues, stacks, feed pumps, feed-water heater, economizers, mechanical draft, and all piping and pipe covering except for condenser water	24.00	12.00
Turbine Room Equipment, including steam turbines and generators, condensers with condenser auxiliaries and water piping, oiling system, etc.	22.00	12.00
Electrical Switching Equipment, including exciters, masonry switch structure with all switchboards, switches, instruments, etc., and all wiring except for building lighting	5.00	2.00
Service Equipment, such as cranes, lighting, heating, plumbing, fire protection, compressed air, furniture, permanent tools, coal and ash-handling machinery, etc.	5.00	2.50
Building, including frame, walls, floors, roofs, windows and doors, coal bunkers, but exclusive of foundations, heating, plumbing and lighting	12.00	4.00
Starting Up. — Labor, fuel and supplies for getting plant ready to carry useful load	1.00	0.50
General Charges, such as engineering, purchasing, supervision, clerical work, construction plant and supplies, watchmen, cleaning up	6.00	3.00
Total Cost, except land and interest during construction	83.75	38.00

The same authorities give the costs of foundations at from \$1.25 to \$4.00 per square foot of building area, depending on the nature of the sub-soil. Table III shows that the ground area of buildings ranges from 0.8 to 2.0 square feet per kw. Building costs range from 8 to 12 cents per cubic foot of space, over-all. Power plant buildings range from 50 to 100 cubic feet per kw.

The writer has correlated miscellaneous data on power plant costs in the form of curves, see Fig. 4. The curves are shown in an additive sense, e.g., for a 12,000 kilowatt plant, boiler room equipment and piping cost \$17.50 per kw., generating plant \$37.00 − \$17.50 = \$19.50 per kw., etc., the total cost except land and interest during construction being \$66.00 per kw.

Operating Cost and Fixed Charges. — The cost of producing electrical energy comprises two groups of items, viz., fixed charges on the investment in the power plant to cover interest, depreciation, taxes and insurance, and the

TABLE V.—COSTS OF BOILER ROOM EQUIPMENT.

Item	Dollars per boiler horse-power	
	High	Low
Boilers, except settings	$11.00	$8.00
Superheaters	3.00	0.00
Stokers	5.50	3.00
Masonry settings of boilers	3.50	2.00
Flues	1.50	0.75

Totals	$50.25	$23.15

cost of operating the plant. Fixed charges on the investment range from 10 to 14 per cent of the investment per annum and are practically independent of the load factor of the station. The amount assignable to each kilowatt-hour is therefore inversely proportional to the load factor and equals, in cents,

$$F = \frac{100\,RI}{8760\,K},$$

where I is the investment per kw. of capacity, in dollars, R is the rate of fixed charges expressed as a decimal fraction and K the annual station load factor expressed as a decimal fraction.

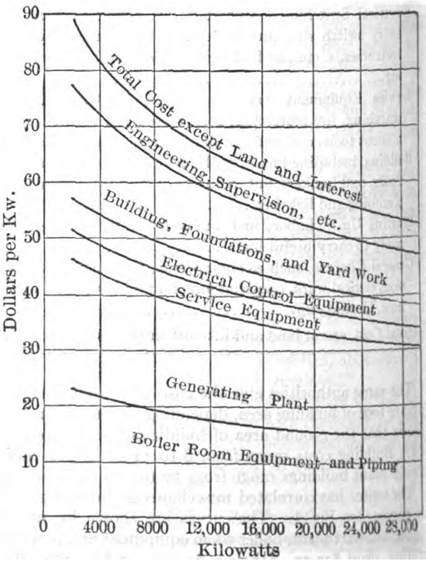

Fig. 4. Approximate Division of Construction Cost of Steam-electric Power Plants. (In additive sense, see text.)

Operating costs include supervision, labor, fuel, other materials consumed and current repairs. The cost of supervision per kw-hr. varies almost inversely

with the load factor. Labor cost per kw-hr. in boiler plants vary in almost direct proportion to the weight of coal burned per kw-hr. Labor cost per kw-hr. in generating rooms varies greatly with the size of the station and the number of units operated, since the number of men required depends more on the number of units of apparatus to be cared for than on the ratings of these units. Large plants are therefore at a large advantage in the item of labor cost. The cost of fuel per kw-hr. varies directly with the price of heat units in the coal burned and inversely with the over-all efficiency of the station. In modern steam turbine stations the cost of supplies other than fuel averages about 20 per cent of the total labor cost. The cost of current repairs in such stations is from $0.75 to $1.50 per annum per kw. of generating capacity. A high load factor is distinctly favorable to good physical efficiency, due to the reduction of stand-by and light-load losses, and to economy in the use of labor. H. G. Stott has pointed out that the production cost per kw-hr. varies inversely with the 4th root of the annual load factor. (*See Proc. A.I.E.E., Vol. 32, p. 1127.*)

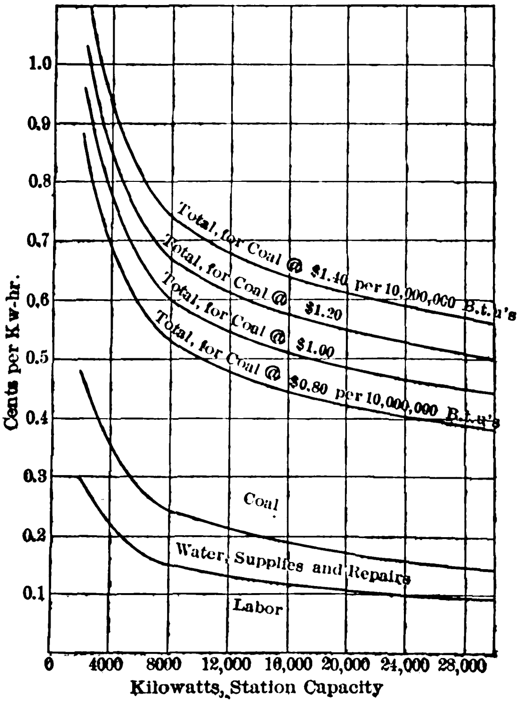

Fig. 5. Approximate Division of Operating Expenses of Steam-electric Power Plants. (In additive sense, see text.)

The writer has correlated the records of the operating costs of a considerable number of railway and public service station having load factors between 25 and 33 per cent, and from these data has prepared the curves in Fig. 5. (For the B.t.u. equivalent of a ton of coal see article on *Fuel*.) These curves are shown in an additive sense, in the same manner as the curves in Fig. 4.

[W. E. Wickenden.]

PRINTING PRESSES, ELECTRICAL OPERATION OF.—(*See also Motors, Industrial Applications of.*) Owing to the great variety of work performed, printing machinery as a rule requires a certain degree of speed variation in order that with a given equipment and operating force, the maximum of high-grade production may be turned out. All necessary speed variations are most readily, economically and satisfactorily obtained with electric drive and control. Each press can then at all times be under instant control, so that the entire time of the operator may be devoted to the work in hand.

Individual drive is particularly applicable to printing establishments, as in this class of service the ratio is small between the power required to drive the machines running idle and when performing actual productive work. With group drive the ratio between average and connected load is high, due to the large and constant character of the friction losses. The economy in power consumption is, therefore, in favor of separately-driven units, which may be shut down when not operating productively.

Printing presses may be divided into three principal classes, viz., job, flat-bed and web presses.

JOB PRESSES. — The job press is the smallest type and requires from ¼ to 1 horse-power, depending upon the size. The motor is generally mounted on or near the press and the drive may involve either a short belt with idler or occasionally some form of friction device. With these presses a speed variation of 60 per cent is often required, which, as a rule, is accomplished by armature control, shunt-wound motors being used with direct-current installations and single-phase repulsion motors with alternating-current.

FLAT-BED PRESSES are considerably larger than job presses and consist of a reciprocating bed containing the type form and a main cylinder on which the impressions are made. The presses require from 2 to 10 horse-power to drive them according to work and size. In the majority of plants a 50 to 60 per cent speed variation is desired, and as these presses require a considerable torque at starting it is usual to provide compound-wound direct-current motors or phase-wound polyphase induction motors. The series winding of the compound-wound motors is generally weaker than for standard motors, 10 per cent being an average value. The speed control is accomplished by field control for direct-current motors and secondary control for induction motors. Most presses of this type allow of mounting the motor under the bed toward the front of the machine and a belt drive with an idler is almost always used.

WEB PRESSES vary greatly in size and come under the head of rotary presses. Different makers have different classifications for the various sizes, such as the number of decks or webs, as 3-deck, 5-deck, 2-web, etc., or according to the number of groups of which they consist, as quadruple, sextuple, octuple, etc. A modern high-speed sextuple press, for example, has three paper rolls and six plate cylinders, each cylinder generally being four plates wide. The plate cylinders revolve at a maximum speed of 300 r.p.m. A wide range of operating speeds must therefore be provided on the controller as the press will often be called upon to operate at speeds as low as one-half of the above.

All of these presses require a slow threading speed, usually about 10 r.p.m. This speed must be steady as the operators have to thread the paper from roll to roll around the cylinder up over the carriers to the folder, and should the press turn by jerks it might mean the loss of a finger, hand or arm. The control must also provide for "jogging" or "inching along" when making the press ready for service, that is turning the cylinders through a small fraction of a revolution so as to bring them to the desired position for putting on the plates. Brakes must

also be provided so that in case of emergency the press may be brought immediately to rest.

Single-motor Equipment. — Motor equipments for web presses are of either the single or two-motor type. The former is used with small and medium-size direct-current units but is not practicable above 30 or 35 horse-power. The principal objection to single-motor equipments is the difficulty in maintaining a constant slow speed, due to the wide variation in torque during any given revolution of the press cylinders. The waste of power in the series and shunt resistances is also a disadvantage, particularly for the larger sizes. Compound-wound motors are generally used with the single-motor equipments so as to provide for the comparatively-heavy starting torque. Speed regulation down to 10 per cent is readily accomplished by connecting a resistance in parallel with the armature circuit which, in combination with the series resistance, gives a fixed slow speed.

Two-motor Equipment. — The two-motor equipment consists, as the name implies, of two motors, one of small size for driving the press at slow speed through a worm-gear reduction, and a large motor to drive the press at the full-producing speed through ordinary direct gearing. The reduction gearing for the small motor is furthermore provided with an automatic ratchet and pawl clutch, which mechanically disconnects the small motor when the press is being accelerated by the large motor.

Either direct- or alternating-current motors may be used with two-motor equipments. When direct-current is used the small motor should be compound wound to insure sufficient starting torque. It is also a common practice to make the large motor compound wound, so as to accelerate the press more easily. With alternating-current the smaller motor may be of the squirrel-cage type but the larger must be of the phase-wound slip-ring type, as a smooth speed variation from the 10 per cent threading speed to the full running speed is most essential.

The capacity of the motors depends on the size and make of the press, and the accompanying table is only intended to give an approximate idea of the power required:

Type of press	Horse-power	
	Small motor	Large motor
Quadruple	5	35
Sextuple	7	50
Double quadruple	Two 5½	Two 35
Double sextuple	Two 7½	Two 50
Octuple	10	70

Control of Two-motor Drive. — Full automatic control in connection with two-motor drive has been almost universally adopted on larger presses. The essentials of this control are the complete automatic control of the press speed from any number of push-button stations located at different points about the press. From any of these stations it is possible to start the press, increase or decrease the speed or stop it. Five buttons are generally provided with each station marked "Fast," "Slow," "Stop," "Safe" and "Run."

Pressure on the "Fast" or "Slow" button causes the press to speed up or slow down until the button is released, when the press will continue to run at the

speed it has then attained. The manipulation of the "Stop" button will immediately stop the press, through the operation of a dynamic brake on direct-current equipments and a solenoid brake on alternating-current equipments. Pressure on the "Safe" button at any station opens the control circuit and renders the equipment inoperative until the "Run" button at that particular station is closed, releasing the "Fast" button. A "Jog" button is frequently also provided, particularly on a-c. equipments, by means of which the cylinders can be inched along to the desired position when plating is done.

[D. B. RUSHMORE, assisted by E. A. LOF.]

PROGRESSION. — (*See also Series, Mathematical.*) There are two kinds of progression, arithmetical and geometrical.

ARITHMETICAL PROGRESSION. — Quantities are said to be in arithmetical progression when they increase or decrease by a common difference.

Let a = first term of the progression,
d = the amount by which any term is greater than the next preceding, i.e., the common difference,
n = the number of terms in the progression.

Then the successive terms of the progression are

$$a,\ a + d,\ a + 2d,\ a + 3d, \text{ etc., to } n \text{ terms.}$$

The last term is

$$a + (n - 1)\, d.$$

The sum of the n terms is

$$\frac{n}{2}[2a + (n - 1)\, d].$$

GEOMETRICAL PROGRESSION. — Quantities are said to be in geometrical progression when they increase or decrease by a common ratio. Let

a = the first term of the progression,
r = the ratio of any term to the next preceding term,
n = the number of terms in the progression.

Then the successive terms of the progression are

$$a,\ ar,\ ar^2,\ ar^3, \text{ etc., to } n \text{ terms.}$$

The last term is

$$ar^{n-1}.$$

The sum of the n terms is

$$\frac{a(1 - r^n)}{1 - r}.$$

[W. A. DEL MAR.]

PUMPS AND PUMPING ENGINES. — (*See also Boilers; Blowers and Compressors; Condensers; Fans; Power Stations; Steam Engines; Steam Turbines.*) Pumps may be classified according to (1) their mode of action as piston, plunger, centrifugal, rotary, jet and direct pressure; (2) their motive power, as engine-driven, turbine-driven, motor-driven, and power-driven (by belt or gearing); (3) the number of cylinders (or their equivalent), as simplex, duplex and triplex; (4) the number of stages or pump elements in series, as single-stage and multi-stage; (5) the mode of connection, as direct-acting, crank-driven and geared. Large steam-driven pumps are usually called pumping engines.

Piston and Plunger Pumps are the most common in use. In the single-acting type, water is taken in on one stroke and discharged on the return stroke. In the double-acting pump water is taken in and discharged on both strokes. In the direct-acting piston or plunger pump the steam piston and the water piston or plunger are both secured to the same piston rod and the steam is used non-expansively. Their steam consumption is consequently high, unless special compensating devices, substitutes for a flywheel, are used, as in the Worthington high-duty and the d'Auria pumping engines. Large piston pumps are usually provided with a crank and flywheel, so that the steam may be used expansively.

Centrifugal Pumps consist essentially of a rotating impeller which draws water in at its center and a stationary casing which guides the water to the discharge outlet. Centrifugal pumps having stationary guide-vanes inside of the casing are called "turbine" pumps. Centrifugal pumps are especially suited for low heads and large volumes, but are also built multi-stage for high heads. They are not as efficient as high-grade pumping engines, but are considerably cheaper.

Rotary Pumps. — Pumps with two parallel geared shafts carrying vanes or impellers which mesh with each other, and other forms of positive-driven apparatus, in which the water is pushed at a moderate velocity, instead of being rotated at a high velocity as in centrifugal pumps, are known as rotary pumps. They have an advantage over reciprocating pumps in being valveless, and over centrifugal pumps in working under widely-varying heads. They are usually not economical, but when carefully designed with the impellers of the correct cycloidal shape, like those used in positive rotary blowers, they give a moderately high efficiency.

Injectors. — The injector is a form of steam pump commonly used for feeding boilers. If a cylindrical tube 1 or 2 inches in diameter is reduced to one-half its diameter, or thereabouts, at one portion of its length, by gradual reduction and enlargement, and a smaller tube or nozzle inserted inside of it, so that the end of the smaller tube approaches the reduced section of the larger tube, then if the larger tube be connected to a supply of water. and steam at considerable pressure be introduced through the smaller tube or nozzle, the water will be drawn into the larger tube and ejected from its outer end with such force as to cause it to overcome the pressure in the boiler supplying the steam, and thus to feed water into the boiler. The apparent paradox of the injector is explained by the fact that the violent rush of steam into the water gives the latter a high velocity and the momentum thereby induced cannot be overcome in a limited space without the exertion of a force greater than that of the steam in the boiler. As a boiler feeder the injector has a remarkably high efficiency, for so much of the heat energy of the steam as is not converted into mechanical work is carried into the boiler as heat in the water, but as a pump for ordinary purposes its efficiency is very low, since less than 1 per cent of the thermal

energy of the steam is converted into work. The usefulness of the injector as a boiler feeder is limited by the fact that it will not handle hot water.

Direct-pressure Pumps. — These are of two types, the pulsometer and the air lift. In the pulsometer the water is raised by suction into the pump chamber by the condensation of steam within it, and is then forced into the delivery pipe by the pressure of a new quantity of steam on the surface of the water. Two chambers are used, which work alternately, one raising while the other is discharging. The air-lift pump consists of a vertical water pipe with its lower end submerged in a well and a smaller pipe delivering air into it at the bottom. The rising column in the pipe consists of air mingled with water, the air being in bubbles of various sizes, and therefore lighter than a column of water of the same height; consequently the water in the pipe is raised above the level of the surrounding water. The pulsometer is used for pumping out pumps, drains, etc., and the air lift for pumping from wells.

PERFORMANCE. — The performance of a pump is usually expressed in terms of steam consumption of the steam cylinder or engine driving it, the indicated horse power of the cylinder or engine driving it (or the brake horse power of the motor in case of a motor-driven pump), the mechanical efficiency of the pump, and the slip.

Useful or Water Horse Power. — Let p = difference in pressure in pounds per square inch between inlet and outlet of pump = pressure in pounds per square inch indicated by gauge on force main $\pm$ pressure in pounds per square inch indicated by gauge on suction main ($+$ if this reads below atmospheric pressure, $-$ if above) $+$ pressure in pounds per square inch corresponding to the distance between the two gauges; H = head in ft. corresponding to p; Q = actual discharge* in cubic feet per minute; W = pounds per minute discharged; w = weight of the fluid per cubic foot. For water at 62° F., w = 62.36 pounds and is about 0.1 per cent greater at 40° F., and 4 per cent less at 212° F. Then the useful or water horse power is

$$P_w = \frac{144\,pQ}{33{,}000} = \frac{pQ}{229} = \frac{pW}{229\,w} = \frac{HW}{33{,}000} = \frac{HwQ}{33{,}000}.$$

For water at 62° F., and approximately at any temperature between 32° and 212° F.,

$$P_w = \frac{pW}{14{,}300} = \frac{HQ}{529}.$$

Slip. — By the slip of a pump is meant the ratio of the difference between the piston displacement and the water delivered to the piston displacement.

Mechanical Efficiency. — By mechanical efficiency is usually meant the ratio of the useful or water horse power to the indicated horse power of the steam cylinder driving it, or to the brake horse power of the motor in the case of a motor-driven pump. Sometimes the useful or water horse power is figured on the basis of the amount of water corresponding to the piston displacement; the actual water delivered is then equal to the piston displacement multiplied by (1 − slip). The power required to deliver water at a given rate in the first case is equal to the useful or water horse power divided by the mechanical efficiency; in the second case the power required is equal to the useful or water

* Q is sometimes taken as equal to the piston displacement, which is greater than the actual water delivered, due to the slip of the water past the piston and valves.

horse power (reckoned on the basis of piston displacement) divided by the product of the mechanical efficiency and (1 − slip). (*See table below.*)

Duty. — The performance of a steam-driven pump is also expressed as the number of foot-pounds of useful work done by the pump (144 pQ × time in minutes) per million B.t.u. in the steam supplied to it above the temperature of the boiler feed water. (If the boiler takes water from several sources at different temperatures, the B.t.u. added by the boiler from each source must be reckoned separately.) This ratio is called the "duty" of the pump. Duty is also sometimes expressed as the useful work in foot-pounds done by the pump per 1000 pounds of dry steam supplied to it.

The efficiency of a pump falls off rapidly with use, due to wear of the moving parts, unless it is kept in first-class condition. The figures in the following table are for average full-load conditions at rated speed in ordinary practice:

EFFICIENCY AND DUTY OF PUMPS.

Type of Pump	Pounds steam per hour per h.p. of Useful Work	Mechanical efficiency	Per cent slip	Duty, million ft. lb. per million B.t.u.
Piston pumps:				
Small duplex, direct-acting	100 to 200	40 to 60	5 to 20	10 to 20
Compound, direct-acting, non-condensing	40 to 80	70 to 90	2 to 20	25 to 50
Ditto with "high duty" attachment	20 to 33	60 to 80	2 to 20	60 to 100
Single cylinder, flywheel, non-condensing	30 to 50	70 to 90	2 to 20	40 to 60
Multi-cylinder, fly wheel, non-condensing	25 to 40	70 to 90	2 to 20	50 to 80
Multi-cylinder, fly wheel, condensing	13 to 20	70 to 95	2 to 20	80 to 160
Direct-connected, motor-driven	....	50 to 80	2 to 20	60 to 80
Geared pumps	....	50 to 90	2 to 20	30 to 90
Centrifugal pumps:				
Single-stage for low heads	22 to 66	40 to 70	....	30 to 90
Multi-stage for high heads	25 to 50	40 to 60	....	40 to 80
Rotary pumps	26 to 50	50 to 80	5 to 20	40 to 75
Pulsometer	100 to 400	....	....	5 to 20
Air lift	....	10 to 40	....	10 to 25

Performance of Injectors. — Kneass, *Theory of the Injector*, states that the pounds of water delivered (w) per pound of steam supplied is equal, very approximately, to the ratio of the B.t.u. per pound in the steam supplied, reckoned from the temperature (t) of the discharge water to the difference between the temperature (t) of the discharge water, and the temperature (t_0) of the suction water. That is, letting r = heat of evaporation, h = heat of liquid, and x = quality of the steam, then

$$w = (rx + h - t + 32) \div (t - t_0).$$

ELECTRIC DRIVE.* — (*See also Motors, Industrial Applications of.*) Since the reciprocating pump is essentially a low-speed machine, limited to about fifty

* By D. B. Rushmore.

revolutions per minute or thereabouts, it requires a speed reduction, as by gearing, for connection to the driving motor. The centrifugal pump, on the other hand, is suitable for direct connection to motors operating at speeds of up to 3500 r.p.m.

Motors for Reciprocating Pumps. — In starting large reciprocating pumps the water may be delivered through a by-pass until the motor is up to speed, when the by-pass is gradually closed and the water delivered into the system. The load at starting, therefore, only consists of the friction losses, and usually does not exceed 25 per cent of the full-load torque. Small- and medium-size pumps may, however, be required to start under full load.

When direct-current motors are used, the compound-wound type is generally selected for single-acting pumps on account of the rather pulsating load, but for double and triplex pumps having steadier load characteristics the shunt-wound type is used to advantage. Both squirrel-cage and phase-wound induction motors are suitable, the latter, as a rule, being selected where it is desirable to reduce the starting current to a minimum or where a somewhat variable speed is required. Synchronous motors may and are frequently used for driving large pumps. By-pass valves must then, however, be provided for reducing the torque at starting as previously mentioned.

Motors for Centrifugal Pumps. — On account of the peculiar characteristics of centrifugal pumps special care is required in the selection of the motor drive. With a reciprocating pump operating at constant speed an increase of the resistance increases the pressure and therefore the load on the motor; but with a centrifugal pump an increase of the resistance reduces the load. The volume of water delivered by a reciprocating pump is not affected by the reduction of the head, but the required power is reduced. A reduction of the head with a centrifugal pump, however, increases the volume of water, and as the efficiency at the same time goes down rapidly, the load increases. It is, therefore, of importance to know what this overload, caused by a reduction of the head, amounts to and the duration of this overload; and the capacity of the motor should as a rule be governed by the low and not the high head conditions.

The condition of starting must also be given careful consideration in selecting the motor. In starting a centrifugal pump the discharge valve may be entirely closed until the motor comes up to speed, so that the motor may start as nearly light as possible. At rest the torque required is small, usually from 15 to 25 per cent of full-load torque, and this drops from 5 to 6 per cent as soon as the machine starts turning over. The pump casing is full of water, however, and as the machine comes up to speed this water is churned around in the casing, causing the motor to load up as it approaches full speed, when with pumps of the usual design it takes from 40 to 50 per cent of full-load torque to drive it even though pumping no water. Shunt-wound direct-current motors and either squirrel-cage or phase-wound induction motors are well adapted for this type of pump and will readily meet the above conditions. A synchronous motor may lead to difficulties unless proper precautions are taken in designing the starting winding and auxiliary starting equipment.

[Wm. Kent.]

PYROMETERS. — (*See also Temperature and Thermometers.*) A pyrometer is any device for measuring high temperatures. By high temperature as here used is meant a temperature beyond the range of the ordinary mercury thermometer, say 350° C. and up. A great number of pyrometric methods have been proposed, the more important of which will be found treated in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*, New York, 1912. The following brief treatment is adapted from this work.

CLASSIFICATION OF PYROMETERS. — The various types of pyrometers may be classified as follows. Some of these are more fully treated in the following sections.

Gas Pyrometer (Pouillet, Becquerel, Sainte-Claire-Deville, Barus, Chappuis, Holborn, Callendar, Day). — Utilizes the measurement of change in pressure of a gaseous mass kept at constant volume. Its great volume and its fragility render it unsuitable for ordinary measurements; it serves only to give the definition of temperature and should only be used to standardize other pyrometers.

Calorimetric Pyrometer (Regnault, Violle, Le Chatelier, Siemens). — Utilizes the total heat of metals, platinum in the laboratory and nickel in industrial works. It was formerly used for intermittent researches in industrial establishments because its employment demands almost no apprenticeship and because the cost of installation is not great. The cost of a metal ball to withstand over 1000° C. prohibits its use above this temperature in industrial works. Other and more convenient types of pyrometers have almost entirely superseded the calorimetric pyrometer.

Total Radiation Pyrometer (Rosetti, Langley, Boys, Féry, Thwing). — Utilizes the total heat radiated by warm bodies. Its indications are influenced by the variable emissive power of the different substances. Convenient for the evaluation of very high temperatures which no thermometric substance can withstand (electric arc, sun, very hot furnaces), or when it is not convenient to approach the body whose temperature is wanted. Can be made self-registering.

Optical Pyrometer (Becquerel, Le Chatelier, Wanner, Holborn-Kurlbaum, Morse). — Utilizes either the photometric measurement of radiation of a given wave length of a definite portion of the visible spectrum, or the disappearance of a bright filament against an incandescent background. Its indications, as in the preceding case, but to a much less degree, are influenced by variations in emissive power. The intervention of the eye aids greatly the observations, but diminishes notably their precision. This method is mainly employed in industrial works for the determination of the temperatures of bodies difficult of access — for example, of bodies in movement (casting of a metal, the hot metal passing to the rolling mill). Can be used to estimate the highest temperatures and is the best method for use above 1700° C. in laboratory and industrial works.

Electric Resistance Pyrometer (Siemens, Callendar, Waidner and Burgess). — Utilizes the variations of electric resistance of metals (platinum) with the temperature. This method permits of very precise measurements to 1000° C., but requires the employment of fragile apparatus. It merits the preference for very precise investigations in laboratories. As a secondary instrument for the reproduction of a uniform temperature scale throughout the range in which the platinum resistance thermometer can be used, to 1000° C. except in very heavy wire, it is unsurpassed in precision and sensibility. It is also now constructed in convenient form for industrial use.

Thermoelectric Pyrometer (Becquerel, Barus, Le Chatelier). — Utilizes the measurement of electromotive forces developed by the difference in temperature of two similar thermoelectric junctions opposed one to the other. In employing for this measurement a Deprez-d'Arsonval galvanometer with movable coil or a millivoltmeter one has an apparatus easy to handle and of a precision amply sufficient for industrial and many scientific uses. With a potentiometer an instrument is obtained of the highest precision, available for use to 1600° C., or even to 1750° C. with proper precautions. This pyrometer was used for a good many years in scientific laboratories, before it spread into general industrial use, where it also renders most valuable service.

Contraction Pyrometer (Wedgwood). — Utilizes the permanent contraction which clayey materials undergo when submitted to temperatures more or less high. It is employed today only in a few pottery works.

Fusible Cones (Seger). — Utilize the unequal fusibility of earthenware blocks of varied composition. Give only discontinuous indications. Such blocks studied by Seger are spaced so as to have fusing points distant about 20° C. In general use in pottery works and in some similar industries.

Other Pyrometers (Hobson, Uhling-Steinbart, Job, Fournier). — There are a number of other pyrometers which have been found suitable in special cases or which for one reason or another have been found convenient in some particular line of work. Among these are the various industrial instruments based on the relative expansion of metals or of a metal and graphite used in air blasts and metal baths and pyrometers based on the flow or on the pressure of air or vapor.

TOTAL-RADIATION PYROMETERS. — These instruments utilize the radiant heat of *all* wave lengths given off by the body whose temperature is to be measured or by an auxiliary body at the same temperature. By means of a focusing device the radiant heat from a small portion of the hot surface is caused to fall upon a suitable detector. Various devices have been used as detectors, but in modern radiation pyrometers the thermocouple in conjunction with a galvanometer, millivoltmeter or potentiometer is almost universally employed. Instead of the thermocouple a spiral bi-metallic spring, with a pointer attached, is used in Féry's *spiral* pyrometer.

Total-radiation pyrometers can be made self-registering by simply substituting for the indicating galvanometer a suitable recording instrument.

Conditions of Use. — To obtain accurate results with a radiation pyrometer it should be sighted upon the bottom of a closed-end tube inserted into the furnace or bath. The radiating properties of the bottom of such a tube approach very closely those of a "black body" (*see Heat and Thermal Properties*); i.e., the total energy radiated upon the receiving device is proportional to the difference in the fourth powers of the absolute temperature of the hot body and that of the receiving device. Since the latter temperature is usually low compared with the temperature of the hot body, the radiation is practically proportional to the fourth power of the absolute temperature of the hot body. Hence, if the relation between the absolute temperature T_0 and the deflection D_0 of the galvanometer attached to the thermocouple is known at one temperature, and the deflection is known to be proportional to the amount of heat falling on the thermocouple, then the absolute temperature T corresponding to any other deflection D is

$$T = T_0 \sqrt[4]{\frac{D}{D_0}}.$$

It should be noted that this law does not apply unless the instrument is focused upon a "black body." If the instrument is focused upon objects in the

open air its readings, if calibrated by the above law, will be too low, due to the selective radiating properties of all materials. However, the instrument may be calibrated by comparison with a standard pyrometer, e.g., a thermoelectric pyrometer, to give true surface temperatures when sighted upon any particular kind of surface, but this calibration will not hold for other surfaces.

Féry Radiation Pyrometer. — In this apparatus a concave mirror (gold on glass) is used to focus the rays upon the thermocouple. The gold mirror may be considerably tarnished without seriously influencing the readings; and if the aperture of the furnace sighted upon is of sufficient size and the telescope in focus, the temperature readings are practically independent of the distance. The instrument takes its final reading very promptly with only slight creep.

Foster has also transformed the Féry telescope into a "fixed-focus pyrometer" by putting the thermocouple and the aperture at the *conjugate foci* of the gold mirror. In a similar instrument recently issued by the Brown Pyrometer Company, the sighting of the instrument is facilitated by the use of a finder such as used with photographic cameras. The Féry pyrometer of constant-focus type has been coupled directly to a long closed-end tube by Whipple, so that the closed end may be plunged directly into the hot region or melted metal.

Thwing Radiation Pyrometer. — In Thwing's apparatus the reflecting mirror is replaced by a conical cone which by multiple reflection concentrates the radiation at its apex on one or more thermocouples in series with a portable galvanometer.

OPTICAL PYROMETERS. — These instruments utilize only the visible portion of the spectrum, and their indications depend on the comparison, by the eye, of the equality of brightness of two images, one of the object whose temperature is sought and the other a standard light source. Such instruments are therefore essentially the same as photometers (*see article on Photometers*). As a rule the comparison is made with approximately monochromatic light, the images being viewed through a colored glass, usually red.

Temperature and Intensity of Illumination. — Wien's Law. — Wien has shown that the intensity of the light given out by a "black body" (*see Heat and Thermal Properties*) may be expressed by the formula

$$I = A\epsilon^{-\frac{B}{T}},$$

where A and B are constants for a *given wave length*, ϵ is the base of the natural system of logarithms and T the *absolute temperature*. In general, however, the energy of a given wave length radiated by a body in the open air is less than that of a "black body," i.e., its emissive power is less than unity, and the emissive power varies with the temperature. The above law, however, is usually assumed to apply to such bodies, and although the temperature as thus obtained may differ from the true (gas thermometer) temperature by from 50 to 100° C., a *consistent* scale of temperature is obtained for any *particular* substance observed.

"Black Body" Temperature. — The temperatures indicated by a radiation pyrometer that has been calibrated against a black body, or on the assumption of the laws of "black body" radiation, are known as black-body temperatures. Thus, were a piece of iron and a piece of porcelain both at 1200°, the optical pyrometer, which used the red light emitted by these bodies, would give, as the temperature of these bodies, 1140° and 1100° C. respectively. This means that iron and porcelain at 1200° C. emit red light of the same intensity as is emitted by a black body at 1140° and 1100° C. respectively.

Féry Absorption Pyrometer (Fig. 1). — The optical system of this pyrometer is shown in the figure. pp' are a pair of absorbing-glass wedges, G is a

mirror with only a narrow central strip silvered over, L is the standard light source, focused on the mirror G by the lens l. The resultant field, when observing a small crucible, is then as shown at ab. r is a red glass in the eye-piece. The instrument has a fixed angular aperture, so that no correction has to be made for focusing or for varying distance from furnace. The range of the instrument may be extended by the use of auxiliary absorbing glasses A, A'. The instrument is movable about a horizontal axis, which is a convenience in sighting.

A setting is made by adjusting the thickness of the absorbing glasses pp' by moving the wedges together by means of a micrometer screw. Let x = setting of micrometer screw, T = absolute temperature, then, assuming Wien's law to apply

$$T = \frac{a}{x+b},$$

where a and b are two constants, for a given set of wedges pp', and can be obtained by observing two known temperatures.

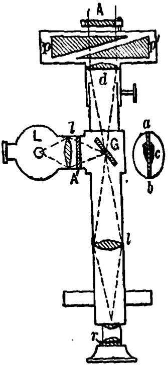

Fig. 1. Féry Absorption Pyrometer

Le Chatelier's Optical Pyrometer. — The Féry pyrometer is a modification of an earlier form devised by Le Chatelier. The latter used an iris diaphragm instead of the wedges, the setting of the instrument being accomplished by changing the aperture. With this arrangement greater sensibility can be obtained, but with the decided disadvantage that the calibration will then hold only for a fixed distance of the instrument from the object viewed.

Wanner Pyrometer (Fig. 2). — In this instrument a Nicol prism is used to vary the relative intensities of the light received from the standard lamp and from the object viewed, the angle through which the prism must be turned to give equal illumination being a measure of the relative intensity of the light emitted from the two sources. The principle is the same as that of a König spectrophotometer (*see Photometers*).

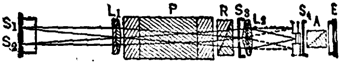

Fig. 2. Wanner Pyrometer

The slit S_1 is illuminated by light from the comparison source, a small 4-volt electric lamp not shown in the figure reaching S_1 after diffuse reflection from a right-angled prism placed before S_1. Light from the object whose temperature is sought enters the slit S_2. If the analyzer is at an angle of 45 degrees with the plane of polarization of each beam, and if the illumination of S_1 and S_2 is of the same brightness, the eye will see a single red circular field of uniform brightness. If one slit receives more light than the other, one-half of the field will brighten, and the two may be brought to equality again by turning the analyzer carrying a graduated scale, which may be calibrated in terms of temperature. Let ϕ = angle through which prism is turned to establish equal illumination, T = absolute temperature of furnace or bath; then, assuming Wien's law to apply,

$$T = \frac{a}{\log(\tan\phi) - b},$$

where a and b are constants determined by calibration. Only two known tem-

peratures need be observed to obtain these constants, but it is safer to plot a calibration curve from several known temperatures.

In the latest form of this instrument the details of its mechanical construction have been improved, and it has been made direct-reading by providing a second scale on the instrument graduated in temperatures, corresponding, of course, to a definite normal point and for a source approximating a black body.

Incandescent Lamp Pyrometers. — In this type of instrument the current through the filament of an incandescent lamp is adjusted until a portion of the filament is of the same color and brightness as the object. When this occurs this part of the filament becomes invisible against the bright background, and the current then becomes a measure of the temperature as given either by a thermocouple or in terms of the intensity of illumination. This principle appears to have been first used by Morse and independently developed by Holborn and Kurlbaum. An absolute match of both color and brightness cannot be made unless monochromatic light is used or unless the lamp filament and viewed object radiate similarly.

Holborn-Kurlbaum Form (Fig. 3). — A small 4-volt electric incandescent lamp L with a horseshoe filament is mounted in the focal plane of the objective and of the eye-piece of a telescope provided with suitable stops D, D, D, and a focusing screw S for the objective. The lamp circuit is completed through a two-cell storage battery B, a rheostat, and a milliammeter.

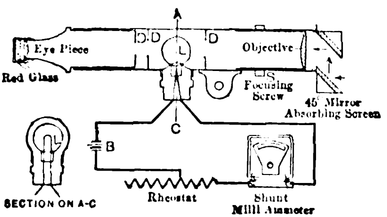

Fig. 3. Holborn-Kurlbaum Pyrometer

The determination of a temperature consists in focusing the instrument upon the incandescent object, thus bringing its image into the plane AC, and adjusting the current by means of the rheostat until the tip of the lamp filament disappears against the bright background, when a previous calibration of current, in terms of temperature for the particular lamp used, gives the temperature by reading the milliammeter. Above 800° C. one or more red absorbing glasses are used.

For the calibration of the instrument it is necessary to find empirically the relation between the current through the lamp and the temperatures for a number of temperatures, and then interpolate either analytically, or more conveniently, graphically. The calibration will be an independent one for each lamp used. If the lamp is not aged its indications may change by as much as 25° C. with time, but after twenty hours' heating at 1800° C. it will undergo no appreciable further changes over a period of many months if not heated above 1500° C.

By the substitution of tungsten for carbon filaments even greater permanence may be had, but the selective radiation of the metallic filament may then be a source of error or inconvenience in certain cases.

Morse and Henning Pyrometers. — The Morse pyrometer is based on the same principle as the Holborn-Kurlbaum, but the construction is somewhat different. The Henning pyrometer is essentially a combination of the Holborn-Kurlbaum instrument with a spectrometer for utilizing monochromatic light.

RESISTANCE PYROMETERS. — These instruments are based upon the variation of electrical resistance with temperature, and are suitable for measuring temperatures throughout the range from the lowest obtainable temperatures to about 1200° C. Platinum wire is usually employed as the resistor, though nickel may be used for temperatures up to 400° C.

Platinum Scale of Temperatures. — The platinum scale of temperatures is defined by the relation

$$p_t = \frac{R_t - R_0}{R_{100} - R_0} \times 100,$$

where R_0 and R_{100} are the resistances of the platinum wire at the temperature of ice and boiling water (760 millimeters mercury pressure) respectively, and R_t is the resistance at any other temperature t. For this scale to agree with the gas thermometer scale would require that the temperature coefficient of resistance of platinum (on the gas scale) be a constant equal to

$$c = \frac{R_{100} - R_0}{100\, R_0}.$$

As a matter of fact the temperature coefficient is not constant but the relation between temperature (on the gas scale) and resistance is

$$R_t = R_0\,(1 + at - bt^2)$$

where a and b are constants. Consequently the platinum temperature and the gas temperature differ by an amount

$$t - p_t = \delta\left(\frac{t}{100} - 1\right)\frac{t}{100},$$

where

$$\delta = \frac{10{,}000\, b}{a - 100\, b}.$$

The fundamental constants of a platinum thermometer are then R_0, c, and δ. These can be determined by measuring the resistance at three known temperatures, *viz.*, melting point of ice, boiling point of water and boiling point of sulphur (444.7° C. on the gas scale). For the purest platinum $\delta = 1.50$ and $c = 0.0039$. The value of δ increases with the amount of impurity.

CORRECTIONS TO t FOR SMALL CHANGES IN δ

Centigrade scale				Centigrade scale			
	Δt for $\Delta\delta = 0.01$		Δt for $\Delta\delta = 0.01$		Δt for $\Delta\delta = 0.01$		Δt for $\Delta\delta = 0.01$
50	−0.002	300	+0.060	550	+0.247	800	+0.560
100	.000	350	.087	600	.300	850	.637
150	+ .008	400	.120	650	.357	900	.720
200	.020	450	.157	700	.420	950	.807
250	.037	500	.200	750	.487	1000	.900

Computations of t from p_t are made by the table on p. 1149, as if the thermometer had $\delta = 1.50$. The above corrections (Δt) are then applied to the computed values of t for the value of δ proper to the thermometer.

Example. Let $p_t = 470.00$, whence $t = 500.00°$ C. by table on p. 1149. If $\delta = 1.52$, the corrected value of t is 500.40° C.

VALUES OF TEMPERATURE CENTIGRADE (t) IN TERMS OF PLATINUM TEMPERATURES (p_t) FOR THERMOMETERS WITH $\delta = 1.500$

p_t	t	Difference for 1° p_t	p_t	t	Difference for 1° p_t	p_t	t	Difference for 1° p_t	p_t	t	Difference for 1° p_t

For a full discussion of the platinum temperature scale and its relation to the gas-thermometer scale, see Burgess and Le Chatelier, *Measurement of High Temperatures.* The brief discussion given above is adapted from this treatise, from which also the tables are taken.

Forms of Resistance Thermometers and Pyrometers. — A complete outfit consists of the thermometer proper or "bulb," the indicating or recording instrument and two or three dry cells for operating the same. Where the indicating or recording instrument is to be in circuit continuously, it is best to operate it from a direct-current lighting circuit or storage-battery system.

With the proper switching device a number of bulbs at widely-separated points may be used with the same indicator or recorder.

Thermometer Proper or Bulb. — Since practically every problem in temperature measurement presents different conditions there can be no general type or form of resistance thermometers. The following descriptions are of some of the thermometers now on the market that have proved satisfactory for certain classes of work.

Resistance thermometers for use below 125° C. are of relatively simple construction, for in this case silk-insulated nickel wire may be used. Such a thermometer is shown in section in **Fig. 4.** This particular thermometer has an over-all length *D* of 10¼ inches, a length of winding *C* of 4½ inches and a diameter *A* of ⅜ inch. The same type of thermometer is also made with a number of different lengths from 3¾ inches over-all to 12¼ inches over-all, and one form, designed to be particularly quick acting, is encased in a thin steel tube ¼ inch outside diameter. This type of thermometer is largely used for the measurement of the temperature of air, solids, concrete, water, and grains and fruit in transit. It may also be used as a wet-bulb thermometer.

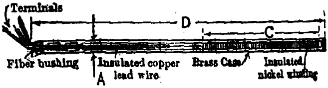

Fig. 4. Resistance Thermometer for Use up to 125° C.

The thermometer shown in Fig. 5 is a platinum resistance bulb for measurement of the highest precision. The winding is of pure platinum wound on a mica cross; the protecting tube is of royal Berlin porcelain. For shop use it is well to protect the porcelain tube with a seamless nickel case. Such a case will maintain its mechanical strength after long exposures to high temperatures. Thermometers of this type may be used up to 1000° C. This type of thermometer is also provided with a special fireproof head and with a steel protecting case in addition to the nickel case. This is necessary where the thermometer is to be used in connection with case hardening.

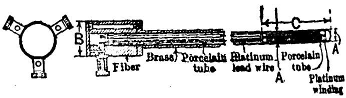

Fig. 5. Thermometer for Use up to 100° C.

The Leeds and Northrup Company make a bulb designed especially for measuring the temperature of generators, transformers, etc. The resistance winding of this bulb is about 3 inches long and is mounted on a flexible stem 30 inches or more in length, the width over-all is ½ inch and the thickness 1/25 inch. This resistance coil is wound non-inductively and is therefore unaffected by neighboring magnetic fields.

Indicating Devices. — The application of the various bridge, potentiometer, differential galvanometer and ohmmeter methods (q.v.) to the measurement of the resistance of the platinum coil and the methods of compensating for the resistance of the leads are described in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*. Two types of indicators are employed: (1) the balance type which requires the adjustment of a rheostat to produce zero deflection of the indicating instrument, the temperature then being read in terms of the balancing resistance, current or p.d., and (2) the direct-reading type in which the deflection of the instrument, read on a properly calibrated scale, gives the temperature directly.

THERMOELECTRIC PYROMETERS. — These instruments consist of a thermocouple and some device for measuring the e.m.f. generated due to the difference in temperature between the hot and cold junctions of the thermocouple, for which the relation between e.m.f. and temperature difference is known. The thermocouple consists of two parallel wires of different materials joined together at one end but insulated from each other throughout their length. The two ends which are joined form the hot junction and the two open ends are usually referred to as the cold junction, although they are not connected directly to each other. The two cold ends are, however, connected electrically through the device used for measuring the e.m.f. generated, thus forming a closed circuit.

Thermocouple Circuits. — The net e.m.f. tending to establish a current in such a circuit as described above is the algebraic sum of all the contact e.m.f.'s (*see Electricity and Magnetism, Principles of*) in the circuit. Wherever there is a change in the chemical nature or physical properties of the conductors forming such a circuit there exists such a contact e.m.f. These various contact e.m.f.'s are functions of the temperature of the transition points, but if the entire circuit is at the same temperature throughout, the net e.m.f. is zero (provided the circuit is formed solely of *metallic* conductors). If, however, *any* transition point is at a higher temperature than another, the net e.m.f. will in general not be zero. Consequently, when a thermocouple is used to measure the difference in temperature between the hot and cold junctions of the couple itself, care must be taken to eliminate the e.m.f.'s due to the temperature differences between the various other transition points in the circuit.

Transition points occur (1) at the junction of any two dissimilar metals; (2) wherever there is a change in the homogeneity of the structure of any of the metals in the circuit, and (3) wherever there is a change in the temperature of the metal, although it may be perfectly homogeneous. To avoid errors due to the e.m.f.'s at the transition points other than the hot and cold junctions of the couple itself, it is necessary to use for the latter metals which give a relatively *high* e.m.f. for a given temperature difference between the two junctions and which are also *homogeneous* throughout, and to so dispose the rest of the circuit that the e.m.f.'s produced therein as the result of temperature differences neutralize one another.

Metals for Thermocouples. — For high-precision thermoelectric pyrometers platinum against platinum-iridium or platinum-rhodium alloys (containing 10 per cent iridium or rhodium) are usually employed. For industrial purposes cheaper metals and alloys are used, such as nickel, copper, iron and alloys of these metals; such couples are usually referred to as *base* metal couples, as contrasted with the *noble* metal couples formed of platinum, iridium, etc.

Thermocouples for Industrial Use. — For industrial use cheap and robust couples are required. Such couples may be made either entirely of the

Fig. 6. Base Metal Couple

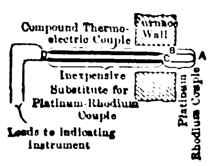

Fig. 7. Compound Couple

base metals or a base-metal couple may be used in series with a short length of a platinum-alloy couple, the latter only being exposed to the highest temperature. In Fig. 6 is shown a convenient form of a simple base-metal couple, and in Fig. 7 one form of compound couple.

Simple base-metal couples can be made of low resistance and their e.m.f. may therefore be measured with a fair degree of accuracy by low-resistance millivoltmeters of robust construction. Base-metal couples made of alloys or metals possessing critical regions, accompanied by the absorption or liberation of heat, are liable to give discordant results on reheating. These effects are particularly marked in couples of considerable size, and are enhanced by varying the depth of immersion of the couple in the test bath or furnace.

Although a very considerable number of base-metal thermocouples has been put upon the market in recent years, there appears to be very little certain

knowledge available as to the exact composition, thermoelectric properties, and behavior of most of them, some of which are quite complex alloys, as, for example, of Ni, Cr, Al and Cu.

Insulation and Protection of Thermocouples. — The two leads should be insulated from one another throughout their length. Use may be made in the laboratory of glass tubes or pipe stems, or of thread of pure asbestos wound about the two wires, by crossing it each time between the two so as to make a double knot in the form of an 8, each of the wires passing through one of the loops of the 8. This is a convenient method of insulation for laboratory use, although ordinary asbestos is likely to contain impurities which will damage the couple. With this arrangement it is impossible to go above 1200° or 1300° C., at which temperature asbestos melts. A more satisfactory insulation, however, is had by means of thin tubes of hard porcelain standing 1500° C. or of quartz tubes standing about 1200° C. Quartz, however, gradually crystallizes and crumbles above 1200° C., and in the presence of a volatile reducing agent, as graphite or hydrogen, volatile silicides are formed above 1200° C., which will destroy platinum.

For industrial installations use may be made of small fire-clay cylinders of 100 millimeters in length and 10 millimeters in diameter, pierced in the direction of the axis by two holes of 1 millimeter diameter, through which pass the wires, or hard porcelain tubes may be used. One or another of the other forms of insulator is added in sufficient numbers. They are placed, according to the case, in an iron tube or in a porcelain tube. The porcelain tube should be employed in fixed installations in which the temperatures may exceed 800° C.

E.M.F.'s of Thermocouples. — By the e.m.f. of a thermocouple is meant the e.m.f. developed in a circuit consisting solely of the metals forming the thermocouple itself; i.e., the e.m.f.'s in the external circuit are not considered. If E_{sa} is the e.m.f. of a couple made of a metal a against any standard metal s, and E_{sb} is the e.m.f. of a couple made of a metal b against this same standard metal s, the e.m.f.'s in each case being for the same temperature of the cold junction (standard temperature is 0° C.) and for the same difference in temperature between the hot and cold junctions, then the e.m.f. of a couple made of a and b is, for these same temperatures

$$E_{ba} = E_{bs} + E_{sa} = E_{bs} - E_{as}.$$

(In this notation *rises* of potential are considered to be in the direction of the subscripts, that is, E_{ba} is the rise of potential from b to a). Consequently the insertion of a metal wire of any material in the circuit of a thermocouple does not change the net e.m.f., *provided this wire is of uniform structure and temperature throughout.* Consequently the hot junction may be soldered with any other metal which will not melt at the temperature to which the junction is exposed.

Electromotive Force Formulas. — No simple relation exists between the e.m.f. (E) of a thermocouple and the temperature difference (t) between the hot and cold junctions. A number of approximate formulas, however, has been suggested. The following, due to Holman, is one of the simplest.

$$E = mt^n,$$

where m and n are constants, the cold junction being kept at 0° C. For convenience in plotting and calculation this may be written

$$\log E = n \log t + \log m.$$

Holman's formula when applied to couples made of platinum and its alloys of iridium and rhodium gives results accurate to about 2° C. for t between

200° C. and 1200° C. Typical values of n and log m are given below (Cambridge Scientific Instrument Company).

	n	log m
Pt against (Pt 90%, Ir 10%)............	1.102	0.895
Pt against (Pt 90%, Rh 10%)..........	1.189	0.526

The values of these constants, however, differ with different makes of couples, and in any particular case should be obtained from the maker as determined by calibration.

Another formula, due to Holborn and Day, is the following,

$$E = -a + bt + ct^2,$$

where a, b and c are constants. Between 300° C. and 1100° C. this formula gives results accurate to 1° C. when applied to couples made of platinum and the various platinum alloys.

Ideal wire (*see Wires, Resistance*) and copper form a very satisfactory couple of relatively large e.m.f. suitable for a range of temperature between 0° and 400° C. With the cold junction at 0° C. the temperature of the hot junction and the e.m.f. are related as follows:

Temp. Hot Junct., °C.........	50	100	150	200	250	300	350
E.m.f., microvolts...	2.3	4.65	7.05	9.45	11.90	14.43	17.08

Thermoelectric Power (H) of Thermocouples. — The thermoelectric power of a thermocouple is defined as the increase in the e.m.f. developed per degree increase in the difference in temperature between the hot and cold junctions. This quantity, which is equal to $b + 2ct$ in Holborn and Day's formula, depends in general upon the temperature (t) of the hot junction; the following values are close approximations within the range stated.

THERMOELECTRIC POWERS OF THERMOCOUPLES
Microvolts per °C. increase in temperature, t in °C.

Thermocouple	Thermoelectric power	Temperature range, ° C.	Authority
Pt and 90% Pt, 10% Rh.............	$4.3+0.0088\,t$	0–1300	Le Chatelier
Pt and 90% Pt, 10% Ir..............	$11.3+0.0104\,t$	0–1000	Le Chatelier
Pt and Ni..........................	$7.8+0.01325\,t$	300–1300	Burgess
Cu and Ni..........................	$24.4+0.016\,t$	0–235	Pécheux
Cu and Constantan *................	$42.3+0.058\,t$	0–320	Pécheux
Pt and Fe (forged).................	$2.5+0.0210\,t$	700–1000	Le Chatelier

* 60% Cu, 40% Ni.

Measurement of E.M.F. of Thermocouples. — Two methods may be used to measure the electromotive force of a couple: the potentiometer method and the galvanometric method (*see Potentiometers; Galvanometers*). The first is the more accurate and is usually made use of in laboratories. The second method is simpler, but possesses the inconvenience of giving only indirectly the

measure of the electromotive force by means of a measurement of current strength.

There are sources of error, however, inherent in the galvanometric method, such as effects of lead resistance and temperature coefficients of leads and galvanometer, which are difficult if not impossible of complete elimination even with the best apparatus available. The potentiometer method, on the other hand, may be made, in so far as the measurements of e.m.f. are concerned, as exact as may be desired, or so that the only outstanding uncertainties are inherent in the thermocouple itself. These uncertainties, such as inhomogeneity, conduction along the wires, variable zero and actual change of e.m.f., are sometimes overlooked, giving rise to illusory accuracy.

The application of these two methods to the measurement of the e.m.f.'s of thermocouples is described in detail in Burgess and Le Chatelier's *Measurement of High Temperatures*.

Cold-junction Correction. — When the galvanometer method is used, it is often not convenient to keep the junctions of the couple to the lead wires of the galvanometer at a definite temperature, although the galvanometer itself may be so far removed from the furnace that its temperature changes are slight. Except in the roughest kind of work, allowance has to be made for the cold-junction temperatures, which may be measured by an auxiliary thermometer.

Calling t_0 the cold-junction temperature for which the instrument reads correctly, t the observed temperature of the cold junction, the correction to apply to the observed temperature readings of the galvanometer, otherwise supposed to read correctly for a given thermocouple, usually lies between $\frac{1}{3}(t - t_0)$ and $(t - t_0)$, depending on the type of couple and the temperatures of both hot and cold junctions. This question has been treated in detail for several types of couple by C. Offenhaus and E. H. Fischer (*Electrochem. and Met. Ind.*, *1908, Vol. 6, p. 362*).

Elimination of Cold-junction Correction. — Bristol has also devised an automatic compensator for cold-end temperatures, shown in Fig. 8, consisting of a small glass bulb and capillary tube partially filled with mercury, into which a short loop of fine platinum wire dips. This is inserted in the thermoelectric circuit close to the cold junction. Changes in temperature cause the mercury to expand or contract, cutting in or out resistance in the circuit. This acts in opposition to the change in e.m.f. with temperature at the cold end, so that a balance may be established if the parts are properly designed.

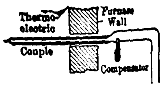

Fig. 8. Bristol's Compensator

In the Thwing instruments the elimination of the temperature variations of the cold ends of the couple, where they can be brought close to the galvanometer, is affected by a device consisting of a compound strip of two metals having unequal coefficients of expansion, so attached to the spring controlling the pointer that the reading of the galvanometer when no current is flowing is the temperature of the surroundings.

CALIBRATION OF PYROMETERS. — The methods employed are described in detail in Burgess and Le Chatelier's *High Temperature Measurements*. In general, the reading of the pyrometer is observed when the fire end is at the melting or boiling point of some solid or liquid. The melting and boiling points which possess the greatest reliability are given in the article on *Heat and Thermal Properties*.

COST, RANGE AND PRECISION OF TYPICAL PYROMETERS. — These items are indicated *approximately* in the table below. The precision stated is on the assumption of proper calibration and careful use.

Type	Range, ° C.	Precision ° C.	Cost, dollars
Nickel ball and calorimeter	100 to 1000	....	40
Féry radiation pyrometer	800 and up	(a)	450
Thwing radiation pyrometer	800 and up	(a)	180
Féry absorption pyrometer	900 and up	(a)	330
Wanner pyrometer	900 and up	(a)	200
Holborn-Kurlbaum pyrometer	900 and up	(a)	royalty basis
Resistance thermometer, " bulb " only	Up to 125	0.3	10
Resistance thermometer, " bulb " only	−200 to 1000	(b)	40
Balance indicator	(c)	(b)	75
Direct-reading indicator	(c)	(b)	45
Thermoelectric pyrometer			
Platinum-iridium couple (24 in. long)	(c)	(b)	30
Base-metal couple	(c)	(d)	10
Seger cones, each	600 to 2000	20–40	0.02
Iron-graphite expansion pyrometer	100 to 800	(b)	15 to 30

(a) Depends on upper limit, (b) depends on range and conditions of use, (c) depends on conditions under which it is used, (d) with millivoltmeter.

[H. PENDER AND H. R. RANKEN.]

RAILS, TRACK AND THIRD. — (*See also Bonds, Railway Track; Railways, Electric, Traction Systems for; Third-rail Systems; Trolley Systems.*) For city streets the track rail of the girder type, as standardized by the American Society of Civil Engineers, has been adopted as standard. Both the 7-inch and the 9-inch sizes are used, but the latter is better adapted to street paving. For interurban and trunk-line work the A.S.C.E. standard* "T" rail is used in sizes ranging from 40 to 100 pounds to the yard. Rails are generally used in 30 ft. lengths, but for city work where low resistance in the return circuit is essential (*see Electrolysis of Grounded Structures*) 60 ft. lengths are used. The longer rail also gives a better roadbed. A new type of rail, known as the Romapac rail, has recently been introduced, in which the base and head are rolled separately the head being crimped on to the base when the rail is installed, with the joints in the head staggered with the joints in the base; see *Bonds, Railway Track.*

RESISTANCE AND CHEMICAL COMPOSITION. — The chemical composition of steel rails with respect to the impurities or elements other than iron (chiefly carbon, manganese, phosphorus, sulphur and silicon) varies over a considerable range, depending upon the process of manufacture. According to J. A. Capp, the specific resistance of an ordinary† steel rail may be taken as a rough indication of the total impurities present. Fig. 1 shows the results of tests on a number of samples of different makes, ranging in total impurities

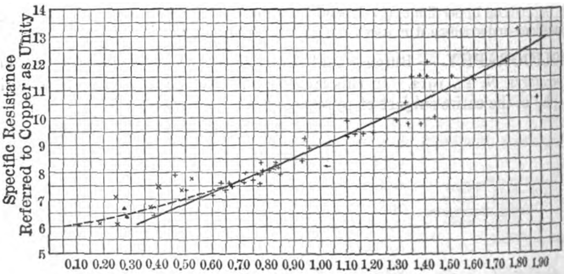

Fig. 1. (From Trans. A.S.M.E.)

from 0.1 per cent to 1.9 per cent, the specific resistance referred to copper as unity ranging from 6.1 to 13.3. The greater hardness caused by the presence of impurities is an advantage in the case of track rails which offsets the disadvantage of low conductivity, but it is usually economical to employ for the third or contact rail a rail of fairly high conductivity.

The compositions given in the tables on the following page are recommended by the authorities quoted.

* A modification of the present standard is now (1913) under consideration. The New York Central and Pennsylvania Railroads have their own standards.

† This does not apply to special forms of rails submitted in the process of rolling to extra heavy pressures.

Allowance for Wear in Resistance Calculations. — Resistance calculations should be made for rails worn down to the weight at which they will be scrapped. It is usual to scrap rails when they have lost from 10 per cent to 20 per cent of the original weight, depending upon the importance of the line. The resistances in the above table should therefore be increased from 10 per cent to 20 per cent.

* To find the resistance of rails of any specific resistance x referred to copper as unity multiply these resistances by x and divide by 8.

Resistance of Romapac Rails. — The conductivity of a rail is affected not only by the chemical composition but also by the treatment in manufacture, especially with regard to the pressure to which it is subjected in the rolling mills. The conductivity of the flange of a rail is greater than that of the head owing to the more direct pressure to which the flange is submitted in the rolling mill. In the Romapac rail, which has a separately rolled head crimped on to the base after the latter is installed, both the head and base are subjected to unusually direct pressure in the rolling mills. Romapac rails tested at Chicago contained about 1.27 per cent of impurities and if rolled in the ordinary way would have a resistivity of about 10.5 times that of copper. They were found to have a resistivity of about 6.5 times that of copper.

A-C. Resistance and Reactance. — See articles on *Trolley Systems, Overhead*; *Signaling, Railway*.

RAILWAYS, ELECTRIC, TRACTION SYSTEMS FOR. — (*See also Automobiles, Electric; Bonds, Railway Track; Car Barns and Inspection Sheds; Cars, Electric; Conduits and Conduit Lines; Control Systems for Railway Motors; Depreciation; Electrolysis; Locomotives, Electric; Locomotives, Steam; Motors; Power Stations; Rails, Track and Third; Rectifiers; Signaling, Railway; Specifications; Substations, Railway; Third-rail Systems; Railways, Energy Requirements for; Railways, Location and Permanent Way for; Transmission Lines; Trolley Systems; Wires and Cables.*) The component parts of a railway system are the following: Generating station, usually three-phase alternating current; high-tension transmission line; substations with transformers and synchronous converters; low-tension distribution system, trolley and feeders; motive power or motor equipments; bonding and feeders for return circuit.

HISTORICAL DEVELOPMENT. — The history of electric traction is given briefly by a few salient epoch-making events.

1835. T. Davenport of Vermont built and exhibited a small model electric vehicle operating on a circular track.

1842. Davidson, Edinburgh, Scotland built a seven-ton car operated by primary batteries and electro-magnets.

1851. G. G. Page operated a small locomotive with primary batteries on the Baltimore and Ohio Railroad at Washington.

1877. S. D. Field in San Francisco operated a small car driven from a stationary remote generator.

1882. J. R. Finney first used the over-running trolley at Allegheny, Pa.

1883. Leo Daft equipped a full-sized passenger train running from Saratoga to Mt. McGregor, together with the over-running-trolley construction.

1886. Bently and Knight introduced the first conduit system in Cleveland, O.

1887–8. Several small installations.

1888. Frank Sprague equipped the Richmond Street Railway and demonstrated the practicability of the system. Bently and Knight equipped a road at Allegheny City. Thomson-Houston system installed at Washington, D. C. Van Depoele brought out the under-running trolley. The directors of the Boston West End System decided to adopt electric traction.

1896. Baltimore and Ohio tunnel at Baltimore electrified; the first electrification of a steam road.

For references to the original papers describing these early installations, see Burch, *Electric Traction for Railway Trains*, N. Y., 1911.

APPLICATIONS OF ELECTRIC TRACTION. — There are certain well defined fields in which electric traction is superior to other methods, the most important of which are the following:

1. Where the frequency of stops is so great as to require a high rate of acceleration in order to make a good schedule speed. If the service requires trains of several cars, any desired number of these cars can be made motor cars and thus a sufficient weight on the driving wheels can be economically secured to give the required adhesion and tractive effort.

2. Where local conditions prohibit the nuisance of the smoke, exhaust gases and noise of steam locomotives, as in cities and tunnels.

3. In heavy trunk-line service where the density of traffic is so great that a high load factor can be obtained with respect to both the power house and distribution system. The *operating* cost of an electric train is always less than the operating cost of a steam train but the *fixed* charges (interest on investment and depreciation) of the electric system are high, for the first cost for the electric equipment, viz., locomotives, motor-car equipment, distribution

system and power house, is much greater than the first cost of steam locomotives, and their accessory equipment. If there are sufficient trains in a system so that the pro rata share of the fixed charges for each train is less than the difference between the operating cost of an equivalent steam equipment and the operating cost of the total electric equipment then electric traction is advantageous.

SYSTEMS OF ELECTRIC TRACTION. — Three different types of motors are in use for electric traction, the direct-current motor, the single-phase commutator motor, and the three-phase induction motor; see articles on *Motors*. The trolley or third-rail voltages (i.e., volts between trolley and track rails or between third rail and track rails) and the motor voltages employed are as follows:

Direct-current Systems. — Trolley or third-rail voltages of 600, 1200 and 2400 volts are in use. The motors for the 600-volt system are designed for full trolley voltage. For the 1200-volt system both 1200-volt and 600-volt motors are used, in the latter case each pair of 600-volt motors being permanently connected electrically. For the 2400-volt system 1200-volt motors are used, each pair of motors being permanently connected in series electrically.

Single-phase Systems. — Trolley voltages (third rails are not used) of from 3000 to 11,000 volts and frequencies of 15 and 25 cycles per second are in use. The trolley voltage is stepped down to from 200 to 500 volts, for which voltage the motors are designed.

Three-phase Systems. — Two trolley wires for each track are required, the two wires and the track forming the necessary three conductors for the three-phase distribution. The usual frequency is 25 cycles per second. The voltages used between the two trolleys and between each trolley and track range from 6000 to 11,000 volts. Transformers are employed to step this three-phase voltage down to from 400 to 600 volts between motor terminals.

Comparison of the Various Systems. — For ordinary street railway service the 600-volt d-c. system is almost universally employed, but for interurban and trunk-line service there is a great difference of opinion as to which of the various systems is the most economical when all the factors are taken into account. The factors which must be considered in comparing the three systems in any particular case are the following:

1. For a given weight and length of trolley or third rail the per cent power loss for a given amount of power transmitted varies inversely as the square of the trolley or third-rail voltage.

2. The higher the trolley or third-rail voltage the fewer are the number of substations required for the same efficiency of distribution and weight of conductor.

3. The higher the trolley or third-rail voltage the more costly is the insulation and supporting structure, and also the greater is the cost of maintenance of the distribution system.

4. Both the first cost and the annual expense of the substations are less for the a-c. systems than for the d-c. systems, since for the former static transformers only are required whereas for the latter rotary converters must be used.

5. The relatively low power factor of a-c. motors (80 to 90 per cent) as well as the relatively low power factor of the line (due to the reactance of the a-c. trolley wire and track return) gives rise to a greater power loss in the a-c. distribution system for the same power delivered than in the case of the d-c. system, and this great loss and lower power factor makes necessary the employment of generating apparatus of greater kv-a. capacity.

6. The 600-volt d-c. motor, for the same horse-power rating and speed, costs less, weighs less and occupies less space than either type of a-c. motor. The high-voltage d-c. motors cost more, weigh more and occupy more space than the 600-volt type.

7. With the a-c. motors transformers are required on the locomotive, which adds to the cost and weight of the locomotive equipment.

8. The 600-volt d-c. motor costs less to maintain and is liable to fewer operating troubles than any of the other motors.

9. With the commutating type of a-c. motor the power lost in the control equipment is practically negligible, since the "potential" type of control can be used. For both the d-c. motor and the induction motor a resistance control is necessary, with consequent loss in power (*see Control Systems for Railway Motors*).

10. The induction motor is inherently a constant-speed machine, and consequently the power input varies directly as the opposing resistance. The d-c. motor and the a-c. commutator motor are inherently variable-speed machines, and the power input varies approximately as the square root of the opposing resistance, the speed at the same time falling off.

11. The three-phase induction motor, when kept connected electrically to the source of power, automatically operates as a generator when the train is going down grade at a speed greater than the synchronous speed of the motor, the motor thus returning power to the line and at the same time acting as a brake preventing any considerable increase in speed. "Regeneration," as this action is called, can also be obtained with the other types of motors but only at increased expense for the additional control equipment required.

Examples of the Use of the Various Systems. — In the following tables are listed (1) all the steam railroad electrifications in this country in 1913; (2) the interurban roads in this country using the a-c. system and (3) those using the high-voltage (over 750 volts) d-c. system; and (4) some of the more important steam railroad electrifications in Europe.

ANALYSIS OF AN ELECTRIC RAILWAY PROJECT. — In the analysis of a particular problem the following general line of procedure is followed:

1. Determine the number and capacity of cars to supply the service desired.
2. Determine the power and energy required to propel these cars at the schedule speed desired; see *Railways, Energy Requirements for.*
3. Select the motors to correspond to the power determined in 2; see *Railways, Energy Requirements for.*
4. Lay out distribution of cars, by train diagrams if necessary; see *Railways, Energy Requirements for.*
5. Calculate the capacity of the low-potential distribution system and of the substations; see *Substations, Railway; Railways, Energy Requirements for; Third-rail Systems; Trolley Systems.*
6. Determine the capacity of the generating stations and transmission system; see *Power Stations; Railways, Energy Requirements for; Transmission Lines.*
7. Estimate the first cost of the system; see articles on the various items involved.
8 Estimate the cost of operation; see articles on the various items involved.
9. Estimate the earning power of the system.

A. In the case of a new road the earning power must exceed the sum of the operating cost and fixed charges by an amount sufficient to pay dividends.

B. In the case of the electrification of a steam road it must be possible to show either: (1) that the result of electrification has been to reduce the operating charges by an amount more than sufficient to pay the fixed charges on the electrical apparatus, or, (2) that the result of electrification will increase the capacity of the road or attract sufficient new business so that the increased earning power will more than balance the increased fixed charges.

[W. I. SLICHTER.]

RAILWAYS, ENERGY REQUIREMENTS AND MOTOR EQUIPMENT FOR. — (*See also Locomotives, Electric; Motors; Power Stations; Railways, Electric, Traction Systems for; Railways, Location and Permanent Way for; Substations, Railway.*) From a consideration of the forces acting on a moving train it is possible to determine the motor capacity and energy required to operate it when the profile and contour of the road, the time table and the characteristics of the available motors are known. The various items are treated in the following sequence:

UNITS AND ABBREVIATIONS. — Throughout this article the various quantities employed will be expressed in the following units unless specifically stated otherwise: distances in feet, weights in tons of 2000 pounds, forces in pounds, speeds in miles per hour (abbreviated mph.), accelerations in miles per hour per second (abbreviated mphps.), mechanical power in horse power, energy in watt-hours.

FORCES ACTING ON A TRAIN. — The forces tending to accelerate a train are the tractive effort developed by the motors and the component of the weight along the track on down grades. The forces which retard the motion of the train are the various frictional forces and the component of the weight along the track on up-grades; also in braking, the frictional force due to the brakes. All the various frictional forces, except the braking resistance, such as track friction, journal friction, air friction, etc., which oppose the motion of a train on a straight track are usually considered together and are referred to as the "train resistance." The extra friction due to track curvature is usually considered as an equivalent up-grade.

Tractive Effort and Draw-bar Pull. — The tractive effort of a motor is the force exerted by the motor at the rim of the driving wheel to which the motor is geared. The tractive effort of a locomotive is the force exerted by the locomotive at the rim of the drivers. The draw-bar pull of a locomotive is the force transmitted through the draw-bar of the locomotive,* and is less than its tractive effort by an amount equal to the resistance due to the rolling friction of the locomotive wheels on the track and the air resistance of the locomotive.

Direct-current motors deliver a uniform tractive effort for a given current; the tractive effort of alternating-current motors pulsates to some extent with the alternations of the current; the tractive effort of a steam locomotive varies

* In the case of a steam locomotive, the draw-bar pull usually refers to the force transmitted through the coupling between the tender and train; i.e., the tender is considered as a part of the locomotive.

from 28 to 50 per cent above and below its average value during each revolution of the drivers.

Train Resistance. — The total train resistance includes the following:

Rolling friction, which depends on the stiffness of the rail and the rigidity of the roadbed, and upon the speed and the weight of the train.

Journal friction, which depends on the speed, weight of the train, temperature and condition of lubrication.

Effect of oscillation and concussion, which depends upon the square of the speed, the weight of the train, and upon the condition of the track and roadbed.

Air resistance, which depends upon the square (approximately only) of the speed, the end area and length of train (number of cars), upon the shape of the end surface, and upon the kind of platforms or vestibules, but is independent of the weight of the train.

In view of the numerous factors which affect the train resistance, it is practically impossible to devise a formula for the resistance per ton of train weight which will be applicable to all types of cars and track construction. Numerous formulas have been suggested, most of which are of the form

$$r = A + Bv + Cv^2,$$

where r = the resistance in pounds per ton, v = speed in miles per hour and A, B and C are constants determined by experiment. The values of these constants naturally depend upon the type of cars, nature of roadbed, number of cars in the train, etc.; consequently the values of these constants as obtained from tests on various types of equipment and track construction differ considerably.

Burch (*Electric Traction for Railway Trains, New York, 1911*) gives the following values for these constants under normal conditions of track and weather. In winter the total train resistance may be as much as 60 per cent greater than the values calculated from the above formula, when these values of the constants are used. An electric locomotive is to be treated as a single car, its weight averaged with the weight of the cars. In the case of a steam locomotive and tender, the tender is to be treated as a car, but the locomotive resistance is to be added as a separate item (*see below*).

Value of *A*. — This constant depends chiefly upon the average total weight of car and load. Let ω = this average total weight *per car* in tons; then for

ω =	15	20	25–30	35	40–45	50	70
A =	6.0	5.5	5.0	4.5	4.0	3.5	3.0

Value of *B*. — This constant depends primarily upon the nature of the track and roadbed and also to some extent upon the weight and type of the car. Burch gives the following values:

Passenger cars on excellent track..................	0.06–0.11
Passenger cars on ordinary track..................	0.10–0.15
Freight cars on ordinary track....................	0.05–0.06

The heavier the car the higher the value of this coefficient.

Value of *C*. — This constant depends primarily upon the air resistance at the head and rear ends of the train and along the sides of the train. It may be expressed approximately by the formula

$$C = \frac{Ka\,(0.9 + 0.1\,N)}{Nw},$$

where a = the cross section of car in square feet, N = number of cars, w = average weight of car and load in tons, and K = 0.0010 for parabolic ends,

0.0020 for wedge-shaped ends, 0.0028 for vestibule cars, 0.0030 for open platforms, 0.0033 for freight cars and 0.0040 for flat fronts.

Tests made on three-car trains in the Boston-Cambridge subway gave a value of approximately 0.0050 for the constant K, the higher value being due to the extra air resistance in the tunnel. *(See Elec. Ry. Jour., 1912, Vol. 40, p. 280.)*

Burch's Table of Train Resistance. — Using the above values of the constants Burch has calculated the following table for train resistance.

TRAIN RESISTANCE FOR ELECTRIC TRAINS

N = number of cars (including electric locomotive, if any);
w = average weight of car loaded, in tons (= total weight of train divided by N);
r = train resistance in pounds per ton;
v = speed in miles per hour;
a = cross section of car in square feet;
A and B constants in the formula; K taken as 0.0030 throughout.

$$r = A + Bv + \frac{Ka\,(0.9 + 0.1\,N)\,v^2}{Nw}. \qquad (1)$$

TABLE I. — VALUES OF TRAIN RESISTANCE

	N	w	A	B	a	Speed in miles per hour 10	20	30	40	50	60

Other Formulas for Train Resistance.—Of the numerous other formulas which have been proposed for train resistance the two most commonly employed are Armstrong's formula

$$r = \frac{50}{\sqrt{Nw}} + 0.03\,v + \frac{0.002\,a\,(0.9 + 0.1\,N)\,v^2}{Nw}$$

and Mailloux's formula

$$r = 3.5 + 0.15\,v + \frac{(0.25 + 0.02\,N)\,v^2}{Nw}.$$

The symbols have the same meaning as above. Armstrong's formula gives considerably lower values than those given by Burch, except for heavy trains; Mailloux's formula gives lower values than those given by Burch except for heavy trains at low speeds, but the difference in most cases is not very great. For other formulas proposed from time to time see Burch, *Electric Traction for Railway Trains*. See also an excellent paper on the resistance of freight trains by E. C. Schmidt in Trans. A.S.M.E., May, 1910.

Resistance of Steam Locomotives.—The American Railway Engineering Association recommend the formula for the resistance of a steam locomotive

$$r_1 = 18.7 + \frac{80\,X}{w_1},$$

where r_1 is the resistance (between cylinder and rim of drivers) per ton weight on the drivers, X is the number of driving axles and w_1 the total weight in tons on all the drivers. Tests by the American Locomotive Company showed that the resistance per ton weight on the drivers is 22.2 pounds.

Train Resistance at Starting.—The formulas given above are not applicable to speeds below about 10 mph. The New York Central tests on electric trains show that the train resistance decreases with decrease in speed to 10 mph., but that as the speed still further decreases the resistance per ton increases. The resistance at starting may be from 6 to 18 pounds per ton, depending upon the condition of the bearings, track, etc., and upon the duration of the stop preceding the starting. These figures also apply to freight trains. Tests on the Rock Island system showed that in the case of a train which had stood overnight in cold weather (i.e., which had become "frozen up"), the starting resistance was 30 pounds per ton. The slack in the car couplings, however, renders it unnecessary for a locomotive to exert sufficient effort to start all the cars at once.

Grades and Curvature.—(*See Railways, Location and Permanent Way for.*) An actual up-grade of G per cent produces a retarding force of 20 G pounds per

ton, and a down-grade of G per cent produces an accelerating force of 20 G pounds per ton. A curve always gives rise to a retarding force which ranges from 0.5 to 1 pound per ton per degree of curvature. Using the higher figure each degree of curvature may be taken equivalent to an up-grade of 0.05 per cent. Note that for angles of curvature up to 12 degrees the angle in degrees may be taken equal to $5730 \div R$ where R is the radius of curvature in feet.

ACCELERATION AND BRAKING. — The permissible rate of acceleration depends upon a number of factors.

1. The rating of the motors; the larger the motors the higher the tractive effort they can develop and therefore the greater the acceleration.

2. The weight on the driving wheels of the car or locomotive; the maximum tractive effort that a motor car can exert without slipping the wheels is from 15 to 20 per cent of the weight on the drivers (*see below under Adhesion Coefficient*).

3. The comfort of the passengers; the higher the acceleration rate the more difficult is it for a passenger to maintain his equilibrium. This also depends to some extent upon the uniformity of the acceleration.

4. To make a given schedule speed with the least amount of energy the acceleration rate should be as high as possible. Very high rates of acceleration, however, are not in general justified on this score, as the increase in the size of the motors required may more than offset the saving of energy.

The following rates of acceleration represent common practice:

TABLE II. — ACCELERATION RATES

Service	Miles per hour per second
Steam locomotive, freight service	0.1 to 0.2
Steam locomotive, passenger service	0.2 to 0.5
Electric locomotive, passenger service	0.3 to c.6
Electric motor cars, interurban service	0.8 to 1.3
Electric motor cars, city service	1.5 to 2.0
Electric motor cars, rapid transit service	1.5 to 2.0
Highest practical rate	2.0 to 2.5

Braking. — The maximum retardation in braking is limited by the comfort of the passengers, and injury to equipment, a retardation of 1.5 miles per hour per second being the usual practical limit for electric or steam passenger trains, although 2.5 miles per hour per second is sometimes attained. For freight trains the braking retardation is from 0.7 to 0.8 miles per hour per second. The higher the rate of braking the less the energy consumption for a given schedule speed.

"Acceleration Constant." — The tractive effort required to give to one ton (2000 pounds) a linear acceleration of one mphps. is 91.2 pounds. To accelerate a train of W tons requires a tractive effort of 91.2 aW pounds to produce a linear acceleration of a mphps., but on account of the accompanying angular acceleration of the rotating parts an additional force is required. This additional force is proportional to the linear acceleration a and also depends upon the radius of gyration (*see Mechanics, Principles of*) of all rotating parts, and upon the gear ratio of the motors (i.e., ratio of number of teeth in gear to number of teeth in pinion). The effect of the moment of inertia may be looked upon either as increasing the effective weight W or as increasing the acceleration

constant, the acceleration constant being defined as the quotient of total accelerating force divided by the product of weight and linear acceleration.

The increase in effective weight (in tons) due to any rotating axle or wheel is $\frac{M}{2000}\left(\frac{K}{r}\right)^2$, where M is the weight in pounds of the part in question, K its radius of gyration (*see Inertia, Moment of*) and r its actual radius, both in feet. Each motor armature adds to the effective weight $\frac{M}{2000}\left(\frac{\rho K}{r}\right)^2$ tons, where M is the weight of the armature in pounds, K the radius of gyration of the armature in feet, r the radius in feet of the wheel to which it is geared and ρ is the gear ratio. The total additional weight W_r is the sum of the above items for all the rotating parts. The total force in pounds required to produce the acceleration of a mphps. is then CaW, where W is the actual weight of the train in tons and $C = 91.2\left(1 + \frac{W_r}{W}\right)$. This quantity C is the corrected acceleration constant, and this corrected value should be used in all calculations.

The acceleration constant is raised by the flywheel effect discussed above by about 5 per cent (i.e., $W_r/W = 0.05$) for heavy cars and locomotives, and between 5 per cent and 10 per cent for light low-speed cars, 8 per cent being an average figure. However, C is usually taken as 100, corresponding to an increase in effective weight of about 10 per cent. A given linear acceleration of a mphps. then requires an accelerating force of $100a$ pounds per ton.

TRACTIVE EFFORT REQUIRED. — Let

F = tractive effort, in pounds per ton, exerted by motors,
G = per cent actual grade (+ for up-grade),
g = degrees of curvature,
r = train resistance, in pounds per ton,
a = acceleration in mphps (− for retardation).

Then the tractive effort required per ton of total train weight is

$$F = 100a + r + 20G + g. \qquad (2)$$

Example. — Given a train of three 45-ton cars moving with a speed of 20 mph. and accelerating at a rate of 1.5 mphps. up a 1 per cent grade on a straight track; what is the total tractive effort required?

Answer: $(100 \times 1.5 + 7.8 + 20 \times 1)\, 3 \times 45 = 24{,}000$ pounds.

GEAR RATIO AND SPEED. — By gear ratio is meant the ratio of the number of teeth in the gear on the wheel axle to the number of teeth in the pinion on the motor shaft. A gear ratio greater than 6:1 is seldom used for railway motors. For a given torque developed by the driving motor, the tractive effort at the wheel rim and the linear speed for a given current depend upon the gear ratio and wheel diameter. Let D = the diameter of the wheel in inches, K = the gear ratio, F = the tractive effort for a given current input; then the tractive effort F_1 for this same current input but for a wheel diameter D_1 and gear ratio K_1 is

$$F_1 = \frac{DK_1}{D_1K}F.$$

If V is the speed corresponding to the tractive effort F for a given motor voltage, then the speed V_1 corresponding to the tractive effort F_1 for the same motor voltage and current is

$$V_1 = \frac{D_1K}{DK_1}V.$$

If the gear ratio is low, the maximum speed will be high and the rate of acceleration low; if the gear ratio is high, the maximum speed will be low and the rate of acceleration high.

For a given motor equipment, train weight, schedule, and profile the energy consumption and temperature rise of the motors depend upon the gear ratio selected, since this in turn determines the amount of coasting; see section below on *Importance of Coasting.* The proper gear ratio can be found only by trial calculation, plotting speed-time and distance-time curves from motor curves based upon different gear ratios, and calculating the energy consumption and temperature rise in the motors as described below.

MAXIMUM POSSIBLE TRACTIVE EFFORT — ADHESION COEFFICIENT. — The adhesion or "tractive" coefficient is the quotient (expressed usually as per cent) of the tractive effort in pounds which will slip the drivers, divided by the weight in pounds on the drivers. Burch gives the values in the following table. The maximum possible tractive effort is the product of the adhesion coefficient (as a decimal fraction) by the weight (in pounds) on the drivers.

TABLE III. — ADHESION COEFFICIENTS

Condition of track	Without sand	With sand
Most favorable condition	35	40
Clean, dry rail	28	30
Thoroughly wet rail	18	24
Greasy moist rail	15	25
Sleet-covered rail	15	20
Dry-snow-covered rail	11	15

Maximum Grade Train can Ascend. — Let

W = total weight of train in tons,
W_d = total weight on all drivers in tons,
p = adhesion coefficient in per cent,
r = train resistance in pounds per ton of total weight,
G = per cent grade,
g = degree of curvature,
a = acceleration in miles per hour per second.

Then the maximum tractive effort which the drivers can exert is $20\,pW_d$ pounds, and therefore $(r + 20\,G + g + 100\,a)\,W$ must be less than $20\,pW_d$, or the maximum per cent grade which the train can ascend is*

$$G = \frac{pW_d}{W} - \frac{(r + g + 100\,a)}{20}. \tag{3}$$

This grade is greater the less the acceleration, or the greater the retardation. The greater the speed before the train strikes the grade, the greater may the retardation be without bringing the train to rest on the grade, and therefore the steeper the grade it may ascend.

* To be exact W_d should be multiplied by $\sqrt{1 - (G/100)^2}$, but except for very heavy grades this correction is negligible.

Example. — Assume no acceleration or retardation and no curvature, a train resistance of 8 pounds per ton, an adhesive coefficient of 15 per cent, and 25 per cent of total weight of train on drivers. Then the maximum grade the train can ascend is $G = 15 \times 0.25 - 8/20 = 3.35$ per cent.

The highest permissible grade is when all the weight is on the drivers, e.g., single cars or trains of motor cars with all axles equipped with motors. On steam freight roads the maximum grade seldom exceeds 2 per cent, and is usually considerably less, except in very mountainous country.

Weight of Locomotive. — The weight of locomotive required to accelerate a train weighing W tons at the rate of a miles per hour per second up a grade of G per cent on a g degree curve against a frictional resistance of r pounds per ton, when the q per cent of the weight is on the drivers and the coefficient of adhesion is p per cent, is given by the following formula:

$$\text{Weight of locomotive} = \frac{5W}{pq}(100\,a + r + 20\,G + g).$$

Example: What weight of locomotive is required to accelerate a 400-ton train at the rate of 0.5 mile per hour per second up a 0.1% grade against a frictional resistance of 8 lb. per ton, when 80% of the weight is on the drivers and the coefficient of adhesion is 20%?

$$\text{Weight of locomotive} = \frac{5 \times 400}{20 \times 80}(50 + 8 + 2) = 75 \text{ tons.}$$

POWER REQUIRED AT GIVEN SPEED. — Let

r = train resistance in pounds per ton of total train weight,
G = per cent grade,
g = degree of curvature,
a = acceleration in mphps.,
v = speed in mph.,
W = total weight of train in tons.

Then the power required *at the rims of the drivers* is $1.99\,v\,(r + 20\,G + g + 100\,a)$ watts per ton, or $p_0 = 2.67 \times 10^{-3}\,vW\,(r + 20\,G + g + 100\,a)$ horse power, total. (4)

The *power input* p_i to the car or locomotive is equal to the power at the rims of the drivers divided by the over-all efficiency ϵ of the controller, motors and gears, i.e.,

$$p_i = \frac{1.99\,Wv\,(r + 20\,G + g + 100\,a)}{1000\,\epsilon} \quad \text{kilowatts} \qquad (5)$$

Efficiency of Motors. — The over-all efficiency of the motors and gears when the motor is operating at full line voltage does not vary considerably for loads ranging from 50 to 150 per cent of rated load. The maximum efficiency is usually at about rated load, and has the values given in Table IV. At 50 and 150 per cent load, the efficiency may be from 3 to 10 per cent less, depending upon the design and the type of motor. The variation in efficiency with load is usually greater with alternating-current series than with direct-current motors.

Average Over-all Efficiency During Controller Period. — The over-all efficiency of the motors and controller depends upon the type of control employed and upon the resistance inserted or the connections made by the controller. Most modern controllers for interurban cars are provided with a current-limiting device which limits the current to a given value, usually the value of the current corresponding to the 1-hour rating of the motor. Under these conditions the *average* over-all efficiency of the motors and controller over the whole of the *controller period* (i.e., from time of starting until full

TABLE IV. — MAXIMUM OVER-ALL EFFICIENCY OF MOTORS AND GEARS AT RATED VOLTAGE.

Horse power, 1-hour rating	Kind of motor	Max. eff., per cent
30–100	D.C. geared	83–88
100–250	D.C. geared	88–89
250–500	D.C. gearless	91–93
50–200	A.C. series geared	70–80*
200–500	3-phase induction geared	85–89

* Including step-down transformers.

line voltage is established across each motor or until all resistance is cut out) may be expressed as follows, on the assumption (which is very nearly exact) that the speed of the motor varies directly as the voltage impressed across its terminals:

Let ϵ = the over-all efficiency of the motors and gears at end of controller period. Then for straight resistance control with direct-current or induction motors the average efficiency during the controller period is $\epsilon/2$; for series-parallel control with 2 direct-current motors the average efficiency during the controller period is $2\epsilon/3$; with 4 direct-current motors first all in series, then 2 in series, then 2 series sets in parallel, and then all 4 motors in parallel the average efficiency during the controller period is $8\epsilon/11$; for alternating-current series motors with voltage control the average efficiency during the controller period (including losses in step-down transformers) is about 0.90ϵ. Hence for a motor having an 85 per cent efficiency at the 1-hour rating and the starting current limited to the corresponding current rating, the average over-all efficiency of the controller, motors and gear during the controller period is

For straight resistance control	43 per cent
For series-parallel control, direct-current motors	57 per cent
For series-series-parallel control, direct-current motors	62 per cent

Example. — Given a train of three 45-ton cars each car equipped with two 200-horse-power direct-current motors. What is the input to each motor if the speed is 30 mph. and the train is accelerating at 1.0 mphps. up a 2-per-cent grade, the track being straight, and full line voltage being across each motor?

Answer: From Table I the train resistance is $r = 10.5$, and from equation (4) the total power output is

$$p_0 = 2.67 \times 10^{-3} \times 30 \times 135\,(10.5 + 20 \times 2 + 100 \times 1)$$
$$= 1627 \text{ horse-power,}$$

or $1627/6 = 271$ horse power per motor. Assuming an efficiency of 87 per cent, the input to each motor is $271 \times 0.746/0.87 = 232$ kilowatts, and the total input to the train $6 \times 232 = 1392$ kilowatts.

If the train accelerates at this same rate from rest to a speed of 30 mph. at the end of the controller period (series multiple control) the grade being 2 per cent throughout, the average output of the motor would be the output corresponding to half speed or 15 mph., or 136 horse power per motor, requiring an average input of $136 \times 0.746/0.57 = 178$ kilowatts, and the average input to the train during the controller period would be $6 \times 178 = 1068$ kilowatts.

SPEED-TIME AND DISTANCE-TIME CURVES. — To determine the energy required to propel a car or train a given distance over a given track in a

given time requires the consideration of a number of factors which can best be taken into account by the construction of various kinds of time curves. Such curves may be constructed with practically any degree of accuracy desired when the profile of the track, the weight of the train, the various resistances, schedule speed, time of stops, etc., are accurately known. Such data are, however, seldom known with any great precision, and consequently elaborate methods of plotting and calculation are seldom justified. Below will be given (1) some results of actual tests, (2) a rough but simple method of approximating the energy requirements, (3) a step-by-step method, which, though tedious in application, is susceptible of any degree of accuracy desired, provided the given data are accurately known, and (4) an analytical method by which the effect of changes in the time of coasting, rates of acceleration and braking, etc., may be predetermined.

The following terminology will be employed:

Speed-time Curve. — A curve showing the speed (in mph.) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve *ABCEF* in Fig. 1. A speed-time curve may be conveniently divided into four parts, namely:

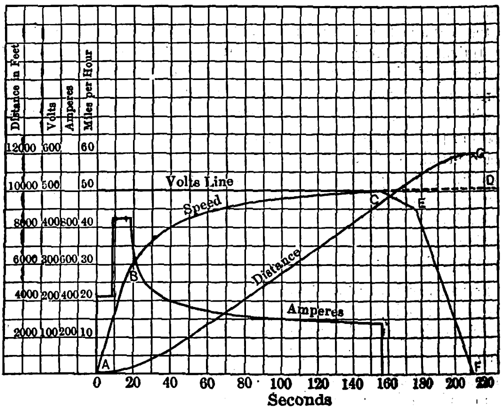

Fig. 1.

Controller Period. — The period from starting until full line voltage is established across each motor; i.e., the portion *AB* of the curve in Fig. 1.

Motor-Curve Period. — The period during which the motor is operating on full line voltage; i.e., the portion *BC* in Fig. 1. The relation between speed and tractive effort during this portion of the run is fixed by the motor characteristics; specifically by the speed-torque curve of the motor and the gear ratio.

Coasting Period. — The period during which the car or train is coasting; i.e., the portion *CE* in Fig. 1.

Braking Period. — The period during which the brakes are applied; i.e., the portion *EF* in Fig. 1.

Distance-time Curve. — A curve showing the distance covered (in feet) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve *AG* in Fig. 1.

Current-time Curve. — A curve showing the line current (in amperes) plotted as ordinates against elapsed time (in seconds) as abscissas; e.g., the curve marked "Amperes" in Fig. 1.

Voltage-time and Power-time Curves. — Curves showing respectively the voltage per motor (or the line voltage) and the power input to the motor (or train) plotted as ordinates against elapsed time (in seconds) as abscissas.

Average Speed and Schedule Speed. — The average speed V is the total distance run L' (in miles) divided by the time (in hours) the train is actually running. The schedule speed S is the total distance run (in miles) divided by the total time (in hours) of the run from one end of the road to the other, including time of all stops at intermediate stations. If the *total* time of all the *intermediate* stops is T_s' seconds, then

$$V = \frac{S}{1 - \dfrac{T_s' S}{3600\, L'}}, \tag{6}$$

where V and S are in miles per hour and L' is the *total* length of route in *miles*.

Duration and Frequency of Station Stops. — The duration of each stop for surface cars ranges from 5 to 10 seconds, for elevated and subway trains from 10 to 30 seconds, for interurban trains from 10 to 40 seconds. The stops per mile are the reciprocal of the average distance in miles between stops.

Average Equivalent Grade (G). — Grades may be taken into consideration by calculating the sum H_1 of all the rises on upgrades and the sum H_2 of all the drops on down grades, and taking for the average "equivalent" upgrade in per cent

$$G = \frac{100\,(H_1 - 0.5\,H_2)}{L}, \tag{7}$$

where H_1 and H_2 are in feet and L is the total length of the route in feet. On a round trip $H_1 = H_2$, and the "equivalent" grade in per cent is

$$G = \frac{50\,H_1}{L}.$$

This method of dealing with grades is equivalent to assuming that half the kinetic energy stored in the train on down grades is utilized in taking the train up the following upgrade. The amount of energy thus rendered available of course will depend upon the amount of braking necessary on down grades to prevent excessive speeds and also upon the location of the stops with respect to the grades. The figure ½ is taken as an approximate average; this figure may be varied as seems reasonable in view of the actual profile.

Average Angle of Curvature (g). — Curves may be taken into account by finding the average curvature, i.e., finding for each curve the product of the degree of curvature by the length of the curve, adding all these products and dividing by the length of the route.

ENERGY CONSUMPTION FROM TESTS. — The table on p. 1176 gives the energy consumption, as found by tests, for a number of typical services. This table will be found useful as a rough check on any calculations made for a specific service. Methods of making such calculations are given in subsequent paragraphs.

APPROXIMATE METHOD OF CALCULATING ENERGY CONSUMPTION.—The following method is based upon simple kinetic principles, and, if certain characteristics of the run are known, gives the actual energy output at the wheel rims. This fact makes the method useful, not only for rough calculations, but also to check calculations made by the step-by-step method.

When the method is applied to checking purposes, the column of Table VI. headed "Actual energy output" should be used, and the input calculated from the known efficiencies. When applied to rough calculations, the column headed "Approximate electrical energy input" should be used. In the latter case the maximum speed and length of run with power on are not known, but it is possible to assume certain values, based upon experience, which will give a rough approximation to the energy required. Let

V = average running speed in miles per hour,
V_m = maximum speed in miles per hour,
L = length of run in miles,
L_p = distance traveled, with power on, in miles,
$n = 1/L$ = number of stops per mile including one terminus,
r = average train resistance, in lb. per ton (Say that corresponding to a speed from 10 to 20 per cent greater than the average speed),
G = average equivalent grade, in per cent,
g = average curvature in degrees,
$K = \frac{V_m}{V}$ = ratio of maximum to average speed; see Table VII,
$Q = \frac{L}{L_p}$ = ratio of length of run to distance traveled with power on; see Table VII.

TABLE VI.—OUTPUT AT WHEEL RIM AND INPUT TO CAR IN WATT-HOURS PER TON-MILE

Energy for	Actual energy output at wheel rims of cars	Approx. electrical energy input to cars
Acceleration	$\frac{V_m^2}{36.2L}$	$\frac{K^2nV^2}{25}$
Train resistance	$\frac{1.99\,rL_p}{L}$	$\frac{2.9\,r}{Q}$
Grades	$\frac{39.8\,GL_p}{L}$	$\frac{57\,G}{Q}$
Curves	$\frac{1.99\,gL_p}{L}$	$\frac{2.9\,g}{Q}$
Total	Sum	Sum

NOTE.—$25 = 36.2\,\epsilon$, $57 = 39.8 + \epsilon$, and $2.9 = 1.99 \div \epsilon$, where ϵ is the efficiency, taken as 0.7. The formula for energy due to curves assumes each degree of curvature to be equivalent to a train resistance of one pound per ton, which is probably high.

TABLE VII.—VALUES OF K AND Q

Stops per mile n	K		Q
	Locomotive Passenger Trains	Single cars, multiple-unit trains and freight trains	All trains
0	1.00	1.00	1.00
0.1	1.18	1.10	1.11
0.2	1.35	1.18	1.24
0.3	1.48	1.25	1.38
0.4	1.60	1.31	1.52
0.5	1.68	1.36	1.67
0.6	1.75	1.40	1.78
0.7	1.82	1.44	1.89
0.8	1.86	1.47	1.99
0.9	1.90	1.50	2.07
1.0	1.93	1.52	2.15
1.2	1.93	1.56	2.24
1.4	1.93	1.59	2.34
1.6	1.94	1.62	2.44
1.8	1.94	1.65	2.52
2.0	1.95	1.68	2.58
2.5	1.95	1.75	2.71
3.0	1.96	1.80	2.81
3.5	1.96	1.85	2.87
4.0	1.97	1.90	2.91
4.5	1.97	1.94	2.95
5.0	1.98	1.97	3.00
over 5.0	2.00	2.00	3.00

(The above method was worked out by D. C. Woodbury and W. A. Del Mar, the table being based upon a large number of actual and calculated runs.)

Example.—A multiple-unit train has a speed (excluding stops) of 25 miles per hour and makes 0.8 stops per mile. It ascends an average grade of 0.143 per cent. What will be its energy consumption in watt-hours per ton-mile?

From Table VII we find for $n = 0.8$, that $K = 1.47$ and $Q = 1.99$. Then using the formulas in Table VI, the results in the table on the next page are obtained, assuming 6.5 pounds per ton for friction.

Efficiency of Run.—The formulas given above enable one to judge the effect upon the energy consumption, of altering any of the principal physical elements upon which the run is based.

From the formulas for kinetic energy it is obvious that a low value of K means a low energy consumption. A low value of K, however, means a "square" speed-time curve; i.e, for low energy consumption the controller, acceleration and braking periods should be as short as possible, or in other words, the rate of acceleration and braking should be as great as practicable.

The quantitative effect of changing any of these variables may be estimated by the analytical method given further on.

Energy for	Watt-hours per ton-mile	
Acceleration..............	$\frac{1.47^2 \times 0.9 \times 25^2}{25} =$	48.5
Train resistance...........	$\frac{2.9 \times 6.5}{1.99} =$	9.5
Grades....................	$\frac{57 \times 0.143}{1.99} =$	4.1
Total......................		62.1

This example worked out by the step-by-step method gave 60.5 watt-hours per ton-mile.

STEP-BY-STEP METHOD OF PLOTTING SPEED-TIME CURVES. — There is no way of exactly predetermining a speed-time curve except by a number of successive trials. That is to say, the time the current is kept on, the time of coasting and the time of braking must each be guessed and it is usually necessary to make a number of trials, by varying the proportion of motor run, coasting and braking, before the given distance is traversed in the desired time.

If the characteristics of the train and its equipment are expressed numerically, the principles of mechanics enable such trial runs to be plotted on paper and the proper proportion of motor run, coasting and braking, selected to make the train travel the desired distance in the given time. For a given motor equipment on a given route it is possible to plot by a step-by-step method these speed-time curves, and then from these curves and the characteristic curves of the motors the various characteristics, such as energy consumption, root-mean-square current, etc., may be determined. The accuracy of this method depends solely upon the accuracy with which the assumed data are known. The necessary data are:

Profile and alignment of road.
Characteristic curves of the motors.
W = total weight of train in tons,
T = the time of run in seconds between successive stops,
I_0 = the permissible starting current, or
a = the acceleration in miles per hour per second during the controller period,
b = the braking rate in miles per hour per second,
r = the train resistance in pounds per ton at any speed.

Determination of Acceleration and Retardation Rates. — From the motor characteristics, which are usually given in the form indicated in Fig. 2, determine the tractive effort and speed corresponding to the permissible starting current. This is usually taken as the current corresponding to the 1-hour rating; in the case of the motor whose characteristics are shown in Fig. 2, this current is 315 amperes, the speed 19.6 mph. and the tractive effort 4300 pounds. If each car is equipped with two motors, the weight corresponding to each motor is half the weight of the car. If the cars weigh 44 tons each, then the tractive effort per ton developed by the motors at this speed is $4300/22 = 195$ pounds per ton. At the point where the motors are changed from series to parallel the speed

will be approximately one-half the speed at rated voltage or 9.8 mph. If the average line voltage is less than the rated voltage, these speeds should be reduced in proportion to the ratio of the actual to the rated voltage. In the case selected the average line voltage is 571 volts; hence the speeds corresponding to the parallel and series points are 18.6 and 9.3 mph. respectively. These speeds and the corresponding tractive efforts are entered into Table VIII.

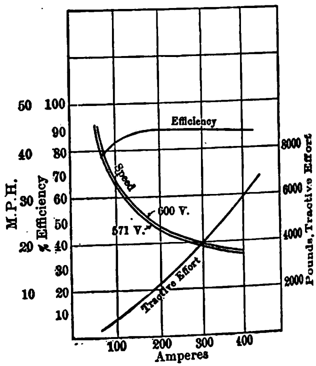

Fig. 2.

From the motor characteristics determine the tractive effort (f) in pounds per ton and the corresponding speeds (v), corrected for line voltage, up to the maximum permissible speed, and enter these in Table VIII. Also enter into this table the train resistance corresponding to the various speeds. In the table given, the train resistance is calculated from Burch's formula for three 44-ton cars, the cross section of each car being 120 square feet, and the constant K is taken equal to 0.0050 (subway service). The formula is then

$$r = 4.0 + 0.13\,v + 0.0055\,v^2,$$

where v is the speed in miles per hour.

The available tractive effort in pounds per ton for acceleration on any grade is then $f - r - 20\,G'$, and the acceleration rate is (assuming an acceleration constant of 100)

$$a = \frac{f - r - 20\,G'}{100},$$

where G' is the "equivalent" grade (including curvature, see above), in per cent. The value of a is calculated for grades of 0, 1, 2, 3, etc., per cent, both up and down, including the largest up and down grade. These values are entered into Table VIII. The maximum speeds are the speeds for which the acceleration becomes zero. These can be obtained by plotting the accelerations against speed, and finding the speed at which the curves cross the speed axis.

Similar calculations should also be made for the retardation on up-grades when the train strikes such a grade, with power on, at a higher speed than the free running speed on the grade, and also for the coasting period when no power is on. When power is on, the friction of the gears and motors is allowed for in the motor tractive effort curve, the tractive effort curve being the gross tractive effort less these losses. The friction of the gears and motors may be taken as approximately 5 per cent of the rated tractive effort, which, in the special case under consideration is $0.05 \times 195 = 10$ pounds per ton. The total train resistance in coasting is then the normal train resistance plus the resistance of gears and motors.

In the Tables a + acceleration signifies an actual increase in velocity, a − acceleration a retardation, or decrease in velocity.

The braking rate is assumed constant, usually $b = 1.5$ mphps.

TABLE VIII. — ACCELERATION RATES

	Speed, mph.	Motor tractive effort, pounds per ton	Train resistance, pounds per ton	Acceleration rates, mphps., = a

	35	0	25	−0.85	−0.65	−0.45	−0.25	−0.05	+0.15	+0.35
	30	0	23	−0.83	−0.63	−0.43	−0.23	−0.03	+0.17	+0.37
	25	0	21	−0.81	−0.61	−0.41	−0.21	−0.01	+0.19	+0.39
	20	0	19	−0.79	−0.59	−0.39	−0.19	+0.01	+0.21	+0.41

NOTE. — The train resistance is assumed to be 6 lb. per ton from zero speed to 9.3 miles per hour.

Construction of Acceleration and Retardation Time Curves. — The next step is to construct a set of acceleration speed-time and distance-time curves, a set of coasting speed-time and distance-time curves, and a braking speed-time and distance-time curve. The construction of these curves is based on the following relations:

Let

v_1 = the speed in miles per hour at time t_1,

v_2 = the speed in mph. at time t_2,

$v = \dfrac{v_1 + v_2}{2}$ = average speed during the interval $t_2 - t_1$,

a_1 = the acceleration in miles per hour per second at time t_1,

a_2 = the acceleration in miles per hour per second at time t_2,

$a = \dfrac{a_1 + a_2}{2}$ = average acceleration during the interval $t_2 - t_1$; (for the first step take a speed corresponding to half the speed at end of controller period),

x_1 = the distance in feet from the starting point at time t_1,

x_2 = the distance in feet from the starting point at time t_2.

Then, for a small change in speed,

$$t_2 - t_1 = \frac{v_2 - v_1}{a} \quad \text{seconds} \tag{8}$$

and the distance covered in this interval is

$$x_2 - x_1 = 1.466\, v\, (t_2 - t_1) \qquad \text{feet} \qquad (9)$$

or, when the speed is plotted against time,

$$x_2 - x_1 = 1.466 \times (\text{Area of speed-time curve between } t_2 \text{ and } t_1). \qquad (10)$$

From equation (8), using the values of a given in Table VIII, the time at which any speed is reached may be calculated. The results of such calculations for the special case under consideration are given in Table IX, and are plotted in Figs. 3, 4 and 5. The distance-time curves are found by planimetering the speed-time curves and multiplying by 1.466 (*see equation 9*), and are also plotted in Figs. 3, 4 and 5.

TABLE IX.—DATA FOR ACCELERATING, COASTING AND RETARDING SPEED TIME CURVES

	Speed v	Total time in seconds to accelerate from rest

The speed during the braking period t seconds *before* the train stops is $v = bt$ and the distance to travel to come to rest is $x = \frac{1}{2} bt^2$.

In the special case of a braking rate of 1.5 mphps.,

$$v = 1.5\,t \text{ miles per hour,}$$

and the distance to travel to come to rest is

$$x = \frac{1.466 \times 1.5\,t^2}{2}.$$

The corresponding curves are given in Fig. 6.

Time Curves for Given Profile and Alignment. — With these four sets of curves the speed-time curve for any given run with this particular equipment may be rapidly constructed. For intermediate grades interpolation may be readily made. In Fig. 7 is given a profile and alignment between two stops. The first step is to make up a table like Table X, dividing the route into sections such that the "equivalent" grade (= actual grade plus, say, 0.05 per cent for each degree of curvature, assuming a resistance of 1 pound per ton per degree of curvature) is the same throughout each section.

TABLE X. — "EQUIVALENT" GRADES

Stop	Distance between stops, feet	Length of section in feet	Per cent grade = G	Radius of curvature in feet	Degree of curvature = g	"Equivalent" grade $G' = G + 0.05\,g$.

B	7321	165	......	....	...	......

For a complete round trip over the entire route the time curves must be plotted for the entire route in both directions. The run in one direction between two stations only will be considered in the numerical calculations given below.

Next lay off on a piece of tracing cloth, see upper part of Fig. 7, a distance equal to the time of run between the two stations (156 seconds in the example), to the same scale as Figs. 3 to 6. The braking speed-time curve can be laid off directly at the far end of the run by placing Fig. 6 under the tracing cloth and tracing the curve. Similarly, by placing Figs. 3 and 4 under the tracing cloth and tracing for the proper distance the curve corresponding to the proper grade, an acceleration curve can be built up until this curve intersects the braking curve. If the total distance, as read off from the corresponding distance-time curve, is greater than the actual distance, it will be necessary to introduce a coasting period of proper duration to make the total distance as read off from the distance-time curves equal to the actual distance. This can be done by placing Fig. 5 under the tracing cloth, and by cut and try finding the proper amount of coasting.

In case there are curves or crossovers, requiring a reduction in speed at certain points, these reductions should be allowed for in plotting the speed-time

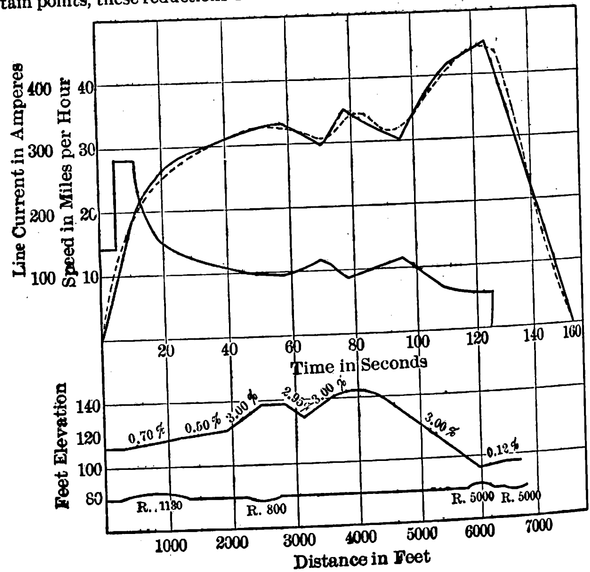

Fig. 7.

curve. A rough rule for the permissible speeds on properly constructed curves is that

$$\text{Speed on curve} = \sqrt{\text{Radius of Curve}},$$

where the radius is in feet and the speed in miles per hour.

The dotted curve in Fig. 7 was obtained from test.

Current-time Curve. — The motor current for any speed may be taken directly from the speed-time curve and motor characteristics. From the motor currents the line current is readily found by multiplying by *half* the number of motors during the *series* portion of the controller period and by the total number of motors during the rest of the time power is on. Current-time curves (line current) for the various grades may also be drawn once for all in the same manner as the speed-time curves in Fig. 3. The curve with the square shoulder in Fig. 7 is the current-time curve for the example considered.

Watt-hours per Ton-Mile. — During the first half of the controller period the input per motor is equal to the product of the current per motor by approximately one-half the line voltage (series-parallel control assumed); during the rest of the time that power is on, the input per motor is equal to the product of the motor current by the line voltage. Hence, calling A the area of the current-time curve from the start until power is shut off, and I_0 the starting current, E the average line voltage, T_1 the seconds duration of the controller period, L the length of the run in miles, M the number of motors and W the weight of the train in tons, then to a fair approximation,

$$\text{Watt-hours per ton-mile} = \frac{EM(A - 0.25 I_0 T_1)}{3600\, WL}.$$

A more accurate, but tedious method, is to plot a power-time curve by multiplying the total current per train at successive intervals of time by the average line voltage during this interval, and then integrating this curve to find the total watt-seconds. This area, in watt-seconds, divided by $(3600\ WL)$ will give the watt-hours per ton-mile. In making such a calculation note that during the series part of the controller period the current per train is equal to the current per motor multiplied by *half* the number of motors.

Root-mean-square Current per Motor. — This may be found by squaring the ordinates of the current-time curve (current per *motor*), plotted as described above, and dividing by the time of run including stops and taking the square root of the quotient. Or, the current-time curve may be plotted in polar co-ordinates, taking time in seconds as the angle in degrees and current in amperes as the radius vector. See Fig. 8. Calling B the area of this curve, the unit of area being the square whose side has a length corresponding to 1 ampere, then the root-mean-square current is

$$I_e = 10.7\sqrt{\frac{B}{T+T_s}},$$

where T is the time that the train is moving and T_s the standing time, both in seconds.

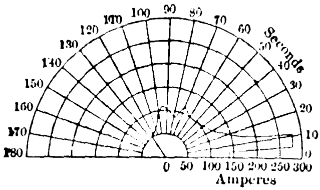

Fig. 8.

Average Motor Voltage. — For a simple run, such as shown in Fig. 1, average motor voltage during the controller period is equal to approximately 55 per cent of the line voltage, assuming 10 per cent of line voltage across the motors at the instant of starting. Let

E = average line voltage,
T_1 = time of controller period, from speed-time curve,
T_2 = time motor is running on full line voltage,
T = total time that the train is moving,
T_s = total standing time.

Then average motor voltage for the entire run is

$$E_m = \frac{0.55\,ET_1 + ET_2}{T+T_s}.$$

For a complex run, where the controller is shut off and put on again during the run, a voltage-time curve may be plotted and the average ordinate obtained by integration.

MOTOR CAPACITY. — A railway motor is usually rated in terms of the output in kilowatts or horse-power which it will give when run for 1 hour at rated voltage with a temperature rise above the surrounding air not exceeding 75° C. in any part of the motor, other than the commutator (*see Standardization Rules*).

The size of motor required for any particular service (i.e. for a given route, schedule, weight of car, line voltage and per cent coasting) depends upon two factors, (1) the motor must be of such a size that the maximum current required will not produce harmful sparking at the brushes or dangerous mechanical stresses in any part of the motor, and (2) the temperature must not rise to a value which will cause the insulation to deteriorate.

Size of Motor Limited by Commutation and Mechanical Stresses — **The maximum current is usually that required at starting, and since the start-**

ing current remains practically constant up to the point where full line voltage is impressed across the motor, the corresponding maximum horse-power output of the motor can be calculated directly from equation (4), when v is taken as the speed at the end of the controller period and W as the weight of the train per motor, i.e., W is taken equal to the total weight of train divided by the number of motors. A safe rule for non-interpole motors in single-car or multiple-unit service is to limit the starting current to a value equal to the rated current. For interpole motors in like service the starting current may safely be 25 to 50 per cent in excess of the rated current.

In locomotive work a heavier starting current is sometimes demanded, and due to the low acceleration rate during the starting period the motor must carry this current for a longer interval than in the case of single-car or multiple-unit service. In selecting a motor for such service, information should be obtained from the manufacturer as to the maximum current which the motor can safely carry during a limited period, say for 5 minutes. This maximum current may be limited by sparking at the commutator, by mechanical stresses, or by local heating of the windings. See also section below on *Size of Motor Limited by Short-time Heating*.

TABLE XI.—RATED AND CONTINUOUS CAPACITY OF WESTINGHOUSE RAILWAY MOTORS

	Type, Westinghouse	Rated H.P.	Rated voltage	Rated amperes	Continuous current capacity		Weight in pounds

Size of Motor Limited by Heating.—The heat developed in a railway motor is carried partly by conduction through the several parts and partly by

convection through the air to the motor frame, whence it is distributed to the outside air. As the temperature of the several parts is thus dependent not only upon their own internal losses, but also upon the temperature of the neighboring parts, it becomes necessary to determine the actual value and distribution of losses in a railway motor for a given service in order to determine with precision what the temperature rise will be; or, *vice versa*, to determine what size of motor will be required to avoid too great a temperature rise.

For ordinary electric railway calculations, however, in view of the other uncertain elements which enter, it is usually sufficiently accurate to assume that the *relative* temperatures in the different parts of the motor are independent of the *relative* values of the copper and core losses. The copper loss, i.e., the rate at which heat is developed in the windings, is proportional to the square of the current, and the core loss, i.e., the rate at which heat is developed in the core, due to hysteresis and eddy currents, may be taken as proportional to the first power of the voltage across the motor terminals (this latter relation being approximate only). When the motor reaches a constant temperature under a constant load, the temperature of any part will then be proportional (approximately) to the total power (kilowatts) lost in the windings and core. Similarly, under a fluctuating load continuing over a long period during which there are no excessively long breaks or excessive overloads, the temperature becomes fairly constant and the rise is proportional to the average power (kilowatts) lost during this period. There will be times at which the temperature rise will exceed this average and times at which it will be less, but on account of the heat storage capacity (or thermal capacity) of the materials of which the motor is made the fluctuations in temperature will be very much less than the fluctuations in the load.

Size of Motor Limited by Average Temperature Rise. — The manufacturers supply information as to the current which any motor will carry continuously (on stand test) without overheating, at various voltages from one-half to full voltage; see Table XI. From this information, making the assumptions noted in the preceding paragraph, it is possible to determine the approximate temperature of the motor for any given run or series of runs. The process is to calculate the root-mean-square current per motor and the average motor voltage for the particular service contemplated, using the methods given above in the paragraphs headed *Root-Mean-Square Currrent per Motor* and *Average Motor Voltage.* Call these values of the r.m.s. service current and average motor voltage I_e and E_m respectively. Let I_c be the continuous-current capacity at a given voltage E_c, as given by the manufacturer (see Table XI), and let T_c be temperature rise corresponding to this continuous rating. (Motors having ordinary fibrous insulation are rated on the basis of a 75° C. temperature rise on stand test, which corresponds to about 65° C. rise in actual service, due to better ventilation; see *Standardization Rules of the A.I.E.E.;* hence for ordinary motors T_c is 65° C.). Let J_c be the corresponding core loss and K_c the corresponding copper loss and $L_c = J_c + K_c$ be the corresponding total electrical losses. Then the total electrical losses corresponding to the average load are

$$L_a = \frac{E_m}{E_c} J_c + \left(\frac{I_m}{I_c}\right)^2 K_c,$$

and the average temperature attained by the motor in service will be approximately

$$T_a = \frac{L_a}{L_c} \cdot T_c.$$

For safe operation the average temperature rise T_a should never exceed the value T_c, which for motors with ordinary fibrous insulation is 65° C.

Approximate Values of J_c and K_c. — When the core loss and copper loss are not given separately, a rough estimate of J_c and K_c may be made by assuming that at rated load (one-hour rating and line voltage) the core loss is, say, ¼th of the total electrical losses. The total electrical losses L_r in kw. at rated load may be found from the characteristic curves of the motor by using the formula

$$L_r = (1.05 - \epsilon)P,$$

where P is the one-hour rating in kilowatts, ϵ the efficiency of the motor with gears, and the 0.05 takes into account the frictional losses in the motor and the gears. Let I_r be the rated current and E_r the rated voltage; then

$$J_c = \frac{L_r}{4}\frac{E_c}{E_r} \qquad \text{and} \qquad K_c = \frac{3\,L_r}{4}\left(\frac{I_c}{I_r}\right)^2.$$

Size of Motor Limited by Short-time Temperature Rise. — When the service is such that the motor must take a heavy current for a comparatively long interval (e.g., a long starting period or a heavy grade for a considerable distance) followed by a like period of light load or no load, the average temperature for the run, as calculated above, may be within the required limits, but the short-time temperature rise may be excessive. This short-time temperature rise depends upon the heat-storage capacity of the motor, i.e., upon the *energy* loss (number of *kilowatt-hours* of heat developed in it) required to raise its temperature one degree, say, assuming no radiation of heat from its surface. The one-hour rating of a motor is an indirect measure of this heat-storage or thermal capacity.

The temperature-time curve during the first hour's application of a load is practically a straight line whose slope is proportional to the load. The rise in temperature of the motor due to a short-time load may then be assumed to be proportional to the *energy* (kilowatt-hour) input during this time, and the factor of proportionality may be obtained from the one-hour rating as follows: Let T_r = the temperature rise at the end of one hour due to a load equal to the one-hour rating of the motor (rated current and rated voltage), L_r = the total electrical losses in kilowatts corresponding to the rated load, L_a = the total electrical losses in kilowatts corresponding to the average load in service (L_r and L_a may be estimated by the method given in the preceding section), L_p = the total electrical losses in kilowatts corresponding to any given short-time or peak load, t_p = the number of minutes' duration of this peak load. Then during this interval t_p the rise of temperature above the average value T_a is

$$T_p - T_a = \frac{t_p\,T_r}{60\,L_r} \cdot (L_p - L_a).$$

T_p as calculated from this formula gives approximately the maximum temperature rise during the run. For safe operation this maximum temperature rise T_p should not exceed the safe limit stated by the manufacturer. For motors with ordinary fibrous insulation T_p should not exceed 75° C.

Final Choice of Motor. — No motor should be employed for a given service which does not meet the above requirements regarding the maximum current and heating limits. A larger motor than that fixed by these requirements may prove the cheaper in the long run, if by using such a motor the energy consumption can be materially reduced by increasing the amount of coasting during the run. In any event the motor should be of sufficient capacity to permit of a reasonable amount of coasting under normal conditions, so that there will be a sufficient margin in which to make up for lost time, due to unexpected slow-downs or extra stops.

ANALYTICAL METHOD OF PREDETERMINING ENERGY AND MOTOR EQUIPMENT. — The following method was suggested by that developed by Cary T. Hutchinson, in two papers in the *A.I.E.E. Trans., Vol. 19, p. 129, 1902,* and *Vol. 22, p. 657, 1903.* In this method a speed-time curve similar in shape to the curve *ABCEF* in Fig. 1 is assumed. That is, the acceleration during the controller period, the train resistance and the braking retardation are all assumed constant, but a "motor-curve" period (*BC* in Fig. 1) is also taken into account, this latter constituting the essential difference between this method and the "straight-line" speed-time curve method frequently employed for approximate calculations. The introduction of this motor-curve period in the calculations enables one to approximate much more closely actual working conditions, and the results are much more accurate. In addition this method enables one to predetermine, without choosing any particular equipment, the effect of rate of acceleration, rate of braking, per cent of coasting, etc.

TABLE XII. — AVERAGE MOTOR CHARACTERISTICS

y = ratio of any given speed to speed at rated input	f = ratio of tractive effort at this speed to rated tractive effort	p = ratio of power input at this speed to rated input
0.80	2.06	1.82
0.85	1.67	1.54

1.90	0.13	0.265
1.95	0.125	0.26
2.00	0.12	0.25

Average Motor Characteristics. — To take into account the motor-curve portion of the speed-time curve it is necessary to consider the speed,

tractive effort and current input characteristics of the motors. However, instead of using the motor characteristics for any specific motor, the average characteristic curves of direct-current motors* given by Mr. Hutchinson are employed, see Table XII. These average characteristics were calculated by plotting the characteristic curves for the various sizes of direct-current motors manufactured by the General Electric and Westinghouse Companies, expressing the various quantities (current, speed, and tractive effort) as fractions of their values at rated load. Such curves are found to lie very close together, which justifies the use of a single set of curves representing the averages for the various motors. Mr. Hutchinson's curves were calculated from the characteristics of non-interpole motors, but have been found to check also quite closely with the curves for interpole motors. It is also found that these curves have practically the same shape irrespective of what point, between 75% and 125% of rated load, on the curves is taken as unity.

Method of Calculation. — The following symbols are employed:

n = number of stops per mile = total number of stops including one terminus divided by the distance between termini in miles,

V = average running speed in miles per hour,

$T = \dfrac{3600}{nV}$ = average running time between stops in seconds,

a = acceleration in miles per hour per second,†

b = braking rate in miles per hour per second,

r = train resistance in pounds per ton corresponding to a speed from 10 to 20% greater than the average speed V,

G = "equivalent" grade in per cent (*see above*),

g = average curvature, in degrees (*see above*),

$c = \dfrac{r + 20G + g}{100}$ = average "effective" coasting retardation in miles per hour per second,

ϵ = over-all efficiency (expressed as a fraction) of motors and gears at rated load; ϵ is about 0.85 for direct-current motors and about 0.75 for alternating-current motors, the latter figure including step-down transformer losses,

s = ratio of total standing time (including stops and lay overs) to total time that the train is moving,

W = total weight of train in tons,

M = total number of motors for the entire train,

E = average line voltage.

* The method is also applicable to alternating-current motors, but average characteristic curves for such motors are not available. They may, however, be readily constructed, or the characteristic curves given for direct-current motors may be used as an approximation.

† When the starting tractive effort is given, then a is to be calculated from the formula $a = (F - r) \div 100$, where F is the tractive effort in pounds per ton and r the train resistance corresponding to a speed from 10 to 20% greater than V. The actual starting acceleration will be greater than this, due to the lower train resistance at low speeds. Vice versa, if the starting acceleration is given, then the calculated tractive effort (and therefore the starting current and horse-power) at end of the controller period will produce a starting acceleration in excess of the assumed value. As far as the energy consumption and heating are concerned, however, these differences in the actual and assumed accelerations will be balanced by the higher train resistance at the higher speeds.

Calculate

$$\beta = \frac{a}{c},$$

$$A = \frac{V}{T} = \frac{nV^2}{3600},$$

$$m = 2A\left(\frac{1}{c} - \frac{1}{b}\right),$$

$$q = \frac{a}{A}(1 + m).$$

Select a value of the ratio

$$x = \frac{\text{time power is applied}}{\text{time of controller period}}.$$

A run of specified distance can be made in a given time with various values of this ratio x, since this ratio depends upon the proportion of the time that the train coasts; i.e., the greater the coasting time the smaller the value of x, see Fig. 1. The less the value of this ratio, however, the greater will be the starting current required, and therefore the larger the motor capacity in order to avoid sparking. By carrying through the calculations for several values of x one can determine the relation between energy consumption, time of coasting and starting current, and, by plotting, find the minimum value of the energy consumption corresponding to the data assumed, see Fig. 9. In typical rapid-transit service (1 or more stops per mile) minimum energy consumption usually corresponds to a value of x between 2 and 5, i.e., for the controller period lasting from 50 to 20 per cent of the total time power is on.

From Tables A to D, pp. 1196 and 1197, find the values of y, λ, u and i* corresponding to the selected value of x and the ratio β. Using these values calculate

$$J = \frac{x + \beta y}{q}, \quad \text{and} \quad H = \frac{\lambda + \beta y^2}{2q}.$$

Then calculate the quantities listed in the following table.

---

* The analytical expressions for x, λ, u and i in terms of y, f and p (see column headings of Table XII for definitions) are

$$x = 1 + \int_1^y \frac{\beta\, dy}{(1 + \beta) f - 1}$$

$$\lambda = 1 + 2\int_1^x y\, dx$$

$$u = \frac{1 + \beta}{18.1\beta}\left[0.75 + \int_1^x p\, dx\right]$$

$$i = 199\left(1 + \frac{1}{\beta}\right)\sqrt{1 + \int_1^x p^2\, dx}.$$

In the expression for u the constant 0.75 is for series-parallel control. For straight resistance control change 0.75 to 1.00 and for series-series-parallel control change 0.75 to 0.69. For a-c. commutator motors change 0.75 to 0.56. Tables A to D were made up by calculating the value of the above expressions graphically, using for y, f and p the values given in Table XII. Similar tables may readily he calculated for a-c. commutator motors, or for any other type of motor whose "percentage" characteristics differ from Table XII.

Speed at end of controller period in miles per hour....	$V_1 =$	$\dfrac{V}{J+\sqrt{m(H-J^2)}}$
Maximum speed in miles per hour................	$V_m =$	yV_1
Watt-hours per ton-mile...........................	$U =$	$\dfrac{unV_1^2}{\epsilon}$
Ratio of total running time to time on controller.....	$X =$	$\dfrac{aV}{AV_1}$
Ratio of coasting time to running time.............	$C =$	$\dfrac{b(X-x)-ay}{(b-c)X}$
Horsepower output at end of controller period......	$P_0 =$	$\dfrac{(a+c)V_1W}{3.74M}$
Starting current per motor *......................	$I_0 =$	$\dfrac{199(a+c)V_1W}{ME\epsilon}$
Root-mean-square current per motor (including stops) *..................................	$I_e =$	$\dfrac{aiV_1W}{ME\epsilon\sqrt{X(1+s)}}$
Average voltage across motor terminals (including stops)..	$E_m =$	$\dfrac{(x-0.45)E}{X(1+s)}$

* For alternating-current series motors insert the power factor (as a decimal) in the denominator of the formula.

Example. — Consider the following example:

Number of stops per mile.....................	$n = 0.938$
Average running speed........................	$V = 28.7$ mph.
Acceleration rate.............................	$a = 1.84$ mphps.
Braking rate..................................	$b = 1.60$ mphps.
Train resistance at 34.4 mph..................	$r = 15$ lb. per ton.
Average equivalent grade......................	$G = 0.22$ per cent
Average curvature.............................	$g = 1.2$ per cent
Average effective coasting retardation...........	$c = 0.21$
Efficiency of motors and gears at rated load.....	$\epsilon = 0.88$
Ratio of standing to running time (20 sec. stops).	$s = 0.15$
Total weight of train in tons..................	$W = 132$ tons
Total number of motors........................	$M = 6$
Average line voltage..........................	$E = 571$

Then

$$\beta = \frac{1.84}{0.21} = 8.76,$$

$$A = \frac{0.938\,(28.7)^2}{3600} = 0.214,$$

$$m = 2 \times 0.214\left(\frac{1}{0.21} - \frac{1}{1.60}\right) = 1.77,$$

$$q = \frac{1.84\,(1 + 1.77)}{0.214} = 23.8.$$

Then (*see above for meaning of symbols*)

20	1140	681	531	462	423	399	380	368	357	350	326	309

actually observed values of the various quantities and the corresponding values taken from the calculated curves in Fig. 9 for a coasting time of 10 per cent.

	Observed	Calculated
Watt-hours per ton-mile	91	88
Horse-power output at end of controller period	249	241
Starting current per motor	370	345
Root-mean-square current per motor	132	131
Average motor voltage	337	350

From Table XI the proper size of motor would be the interpole motor No. 300, which is rated as 200 horse-power at 550 volts. The motor actually used was a Westinghouse motor, designated as 300 – *B*, and rated at 225 horse-power at 600 volts. The temperature rise from test, after 13 hours in service, was

Armature	65° C.
Commutator	75° C.
Series field	46° C.
Interpole field	52° C.
Frame	37° C.

Importance of Coasting and Selection of Gear Ratio.—A study of Fig. 9 shows that a much less energy consumption would be required for a coasting period of 50 per cent instead of the actual coasting period of 10 per cent, namely 72 watt-hours instead of 88 watt-hours. The starting current required in order to obtain this higher coasting time is 406 amperes instead of 345 amperes, or an increase in the starting current of 18 per cent. If no change in the size of motor were made, this would require approximately the same percentage increase in the gear ratio. The root-mean-square current would increase from 131 to 150, but the average motor voltage would drop from 350 to 170. The motor could therefore probably operate at this higher gear ratio without seriously overheating, but it would be safer to use a larger size motor, particularly as the starting current of 406 amperes is also close to the safe commutating limit.

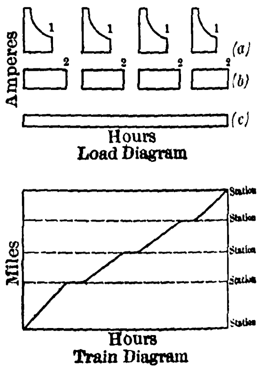

Fig. 10.

TRAIN AND LOAD DIAGRAMS.—The current-time curve for a train making a number of stops may be represented as shown by (*a*) in Fig. 10. On a railway line where there are several trains, the total current may be obtained by placing the current curve for each train at its proper place in the time scale, and adding the ordinates of the curves. Such a process is very tedious and unnecessary where there is a large number of trains. In such cases the high and low parts of the curves become staggered with respect to one another more or less according to the laws of chance, so that each current curve may be replaced by a rectangle of the same area but with a base extending over the entire running time as shown by (*b*) in Fig. 10.

When this is done the kilowatts and amperes per train are derived from the watt-hours per ton-mile by the following formulas:

$$\text{kilowatts} = \frac{WV}{1000} \times (\text{watt-hours per ton-mile}),$$

$$\text{amperes} = \frac{WV}{E} \times (\text{watt-hours per ton-mile}),$$

where

W = weight of train in tons,

V = average running speed (excluding stops) in miles per hour,

E = line voltage.

The time when the current is cut off is indicated by 1, and that when the train stops, by 2, in Fig. 10.

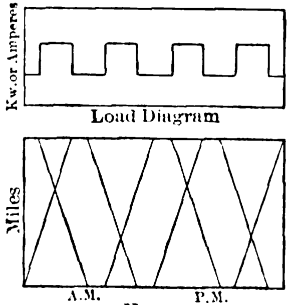

Fig. 11.

Another approximation, which is even more often used, is to replace the series of rectangles shown at b, by a single rectangle as shown at c in Fig. 10. The area of this rectangle will be equal to the sum of the areas of the smaller rectangles or current curves. Using this approximation, kilowatts or amperes may be obtained from the above formulas, taking, however, V to be the schedule speed (i.e., speed including stops). The procedure is to plot a train diagram showing when each train comes on and off the line, neglecting intermediate stops, as shown for a simple case in Fig. 11. Each time a train comes on or off, the corresponding kilowatts or amperes are added to, or subtracted from, the load diagram.

Power Required for Car Heating and Lighting. — In addition to the energy required for propelling the cars, a very appreciable amount is also required in the winter, for heating them, and a small amount at night for lighting. In making up a load diagram this energy should be included.

The average power for car heating varies, of course, with the climate and time of year. The following figures represent usual requirements in the northern parts of the United States:

TABLE XIII. — HEATING AND LIGHTING OF CARS

Length of car, feet	Average* kw. for lighting	Average† kilowatts for heating	
		Average conditions	Severe conditions
14–20	0.25	3.5	4
20–28	0.35	4.5	5.5
28–34	0.55	5.5	7.5
34–40	0.70	7.5	10.5

* During the hours lights are on, using Tungsten lamps.
† During the time car is in service.

Substation and Power-station Loads. — The load diagram obtained as described above gives the total load at the trains. To obtain the load at a sub-

station, the kilowatts or amperes must be increased by a suitable amount to allow for the losses in the distribution system. The load diagram of the power station should allow for all transmission and distribution losses between the power house and substation (*see Power Stations; Substations; Third-rail Systems; Trolley Systems*), and also for all auxiliary power, such as that required for station lighting, shop machinery, etc.

[W. A. Del Mar and H. Pender.]

RAILWAYS, LOCATION AND PERMANENT WAY FOR.— (*See also Railways, Energy Requirements and Motor Capacity for; Railways, Electric, Traction Systems for; Third-rail Systems; Trolley Systems.*) There are four general steps in the determination of the location of a railway, (1) the reconnoissance, which is a personal examination by the locating engineer of the country through which the railway is to run, (2) a preliminary survey and investigation more particularly of the topographic features of the proposed road, (3) office study of the data obtained in (1) and (2), and (4) the field location and the preparation of final location plans.

RECONNOISSANCE. — First a careful examination of the country should be made, with a view not only of obtaining a line which will be reasonably straight and as free from grades as possible, but also with a view of selecting a line or lines which will earn a suitable revenue. An electric railway reconnoissance calls for a much more detailed study of the country than a steam railroad location and a very much more detailed study of the amount of population, its growth, and the likelihood of the population making use of the proposed line. The adapting of an electric line to take in the various intermediate centers of population is practically a necessity if the income of the line is to be sufficient to take care of the investment. The engineer should therefore realize fully that the commercial and financial matters relating to the road are more important than the engineering problems, and should always bear in mind that the road is constructed for the purpose of selling transportation.

Electric railway locations are divided in general into two classes: those which are operated on the public highways, and those which are operated upon their own private rights of way, where they are free to make the fastest practicable schedules. Speed and comfort must be considered. Both of them are, as a rule, better obtained on private locations. It is essential in this reconnoissance for the engineer to make a careful estimate of the probable gross income of the road, as well as to choose two or three lines which will later on be investigated by preliminary surveys.

PRELIMINARY SURVEY. — After the favorable lines have been determined by the locating engineer in his reconnoissance, a party is sent into the field to make a preliminary survey. This is usually a linear traverse run by transit and tape. After this a level party determines the profile of this line, this party being followed by a topographical party which sketches in the 5-foot contours, the locations of brooks, highway crossings, the number and kinds of industries located within say a mile or so of the line, the location of existing recreation points and picnic grounds, as well as the possible location and development of those which do not now exist. The engineer running the preliminary line should keep in mind that the railroad is built for the convenience of the public and that any inconvenient detail of the road will have a material effect upon its gross income.

The topographical party should note the character and property value of buildings or other structures which the line may affect, the character of soil (whether rock or gravel), the location of possible borrow pits, etc. In some locations the topographical features should extend a considerable distance from the transit line; in other locations, where, for example, the line is passing through a narrow valley, the topographical features need not be taken very far from the transit line. While the line should be as straight as possible, some curves are necessary. In locating curves consideration should be taken of the fact that electric traction permits of very rapid acceleration and retardation, and therefore sharper curves are permissible than in steam railroad practice because of the shorter time required to pass around it, even at the

slower speed rendered necessary because of its greater curvature. The time lost in passing around the curve as well as the permissible speed are factors which should be taken into consideration. Roughly speaking, a safe rule is that the speed on curves in miles per hour can be equal to the square root of the radius in feet.

OFFICE STUDY. — On the preliminary map an accurate paper location is drawn and an estimate is made of the cost of the road and of the probable gross earnings, as well as of the fixed charges and the cost of operating and maintaining. This study is one of great importance and if the reconnoissance and preliminary survey are not thoroughly accomplished, errors in judgment may very easily creep into this part of the work. The office study shows the final alinement and the proposed grades of the road.

FIELD LOCATION. — After the completion of the office study the line is finally located in the field. Field location requires running out the line by straight lines and curves, using easement curves at the beginning and end of all changes in direction; the preparation of property maps showing the location required for the railway and all parcels of property affected by actual takings for slope easements; as well as studies of grade crossing eliminations where they are necessary. At this time soundings or borings are taken for bridges or other structures. Cross sections are made of the line, from which careful estimates are made. These cross sections are used in computing the final payment for the work of construction.

Locations in Existing Highways. — Such locations usually have the great advantage of easy grades which frequently cannot be so cheaply obtained upon private land. Locations in highways have the disadvantage of requiring much slower speed. Where such locations are made it is necessary to survey the highways as laid out by the proper officials, and not infrequently it is necessary to consider the widening of such highways by takings on either side. The electric road, for example, may be a 2-track road laid out in the center of the roadway, in which case the road would possibly occupy nearly the full width of the existing highway. In this case the electric road would be required to purchase additional property on either side and probably to build roadways for other vehicles in lieu of the portion which the electric line occupies. When this is done high speeds can sometimes be maintained. Where the electric road occupies one side of an existing highway, the speed often has to be reduced to a relatively low rate. This affects the amount of traffic which the road will attract and thereby reduces the gross earnings.

DEFINITIONS OF TERMS USED ON RAILWAY MAPS AND PROFILES. — Some of the more common terms are defined below.

Curves. — A curve is generally composed of successive arcs of circles joining two straight lines or tangents. When these arcs are of varying radii decreasing with the distance from the tangents the curve is said to be compounded or spiralled. To insure smooth riding the curve should begin with a large radius and gradually grow sharper until the circular part is reached. At the same time the outer rail should be gradually raised (see below) until it reaches its maximum elevation. A curve so built is called an easement curve. Curves, if properly eased, may be run at full speed. On high-speed lines curves sharper than 10 degrees should be avoided.

The following terms are in general use:

The point of curvature (P. C.) is the beginning of the curve, and the point of tangency (P. T.) is the end of the curve, going in the direction of the surveyor's stationing on the line.

The point of intersection (P. I.) is the point where the two tangents through P. C. and P. T. intersect.

The tangent distance is the distance between the P. C. or P. T. and P. I.

The degree of curvature is the angle subtended at the center of a curve by a chord 100 ft. long. Up to a curvature of 12 degrees the radius of curvature may be found to a close approximation by dividing 5730 by the degree of curvature. The exact relation between the degree of curvature C and the radius R is

$$R = \frac{50}{\sin \frac{C}{2}}.$$

The middle ordinate is the perpendicular distance from the center of a chord to the curve.

Elevation of Outer Rail on Curves.—The outer rail on curves is raised above the inner an amount depending upon the velocity of cars and the degree of the curve. This elevation must be gradually attained. The amount of elevation required in order to make the weight of the car just balance the centrifugal force on the curve is

$$E = \frac{DV^2}{32.2\,R} \text{ feet,}$$

where D is the distance between center lines of the two rails (not the track gage), V the speed of car in feet per second, and R the radius of curvature in feet. For standard track gage, viz., 4 feet 8½ inches from inside edge of the *head* of one rail to the inside head of the other rail, and taking $R = 5730/C$, where C is the curvature in degrees, the above expression for the elevation becomes

$$E = 0.000325\,V^2C \text{ inches.}$$

Grades. — A railroad grade is expressed in per cent, this per cent being the number of feet vertical rise in a horizontal distance of 100 feet; i. e., a 4 per cent grade means a rise of 4 feet in a horizontal distance of 100 feet. Calling L the distance in feet along the track and H the vertical rise in feet in this distance, the per cent grade may also be expressed as

$$G = \frac{100\,H}{\sqrt{L^2 - H^2}},$$

which for a grade less than 10 per cent is equal to $100\,H/L$ with an error of less than 1 part in 100.

Grades should be as small as financially practicable. It may be cheaper to operate over a grade than to pay interest on the sum needed to reduce it. Some steam road grades are as steep as 4 per cent, but such grades are extremely costly to operate. Two per cent is about the limit for steam roads and most roads try to keep grades down to about 0.5 per cent. On electric lines operating single trolley cars grades as steep as 10 per cent exist, but no grade over 6 per cent ought to be used unless it is absolutely unavoidable.

Virtual and Momentum Grades. — A driving force or tractive effort is required to accelerate a train, and a driving force or tractive effort is required to cause a train to ascend a grade at constant speed; hence an increase of the speed of the train may be considered, as far as the motive power is concerned, as equivalent to an up-grade. *Vice-versa,* a decrease of speed may be considered as equivalent to a down-grade. The energy required to give the train a speed of v miles per hour is the same as the energy required to raise it a height of $0.0334\,v^2$ feet. Hence, if to the actual elevation of the profile at each point is added a height of $0.0334\,v^2$ feet, where v is the velocity of the train at this

point, and a line is drawn showing the sum of the actual elevation and this velocity head at each point, this line may be looked upon as the "virtual profile" of the road, and the slope of this virtual profile, at any point, i.e., the change in its elevation per hundred feet, is called the "virtual grade" at this point.

The virtual grade at any point on an actual up-grade will be less than the actual grade, if the speed of the train is decreasing as it passes this point; the grade in this case is sometimes called a "momentum grade." That is, if the train has a high speed when it strikes an up-grade, and the operating requirements of the division will permit of a slowing down of the train as it ascends the grade, then the effective or virtual grade will be less than the actual grade. Under such circumstances a given locomotive can pull a given train up a short steep grade on which it could neither start this train nor pull it at constant velocity. A momentum grade must be comparatively short.

Ruling Grade.—The limiting or ruling grade on a division is that grade which limits the weight of the train which can be hauled over this division by the regular motive-power unit. Ordinarily, it is the maximum grade on the division, but if *momentum* grades are relied upon, the ruling grade might be the maximum virtual grade. Reliance upon momentum grades is not always considered good practice, since a heavy train which might get over this grade if it strikes the grade with sufficient momentum, cannot start on this grade if it should have to stop on the grade due to some emergency. When steep grades occur at only one or two places in a division it is sometimes economical to use helper engines on these steep grades, thus making possible the hauling of heavier trains, the weight of train then usually being limited by maximum grade on the remainder of the division.

Switches, Frogs, Cross-overs, Etc.—A switch is an arrangement of rails, which permits a car or train to pass from one track to another. A cross-over consists of a pair of switches connected by a short piece of track in such a way as to allow a car or train to pass or cross over from one track to another parallel one. A turn-out or siding is a short length of track parallel to the main track and connected thereto by a switch at each end; when used as a means of passing cars or trains it is usually called a turn-out, and when used primarily for storing cars or loading it is called a siding.

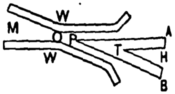

Fig. 1.

A frog, Fig. 1, is that part of the switch where the two inner rails cross each other, and is so designed as to allow the flange of the wheel to pass over without "riding up" on the rail. A guard rail is set close to the switch rail opposite the frog. The lead of a frog is the distance of a frog from the frog point P, see Fig. 1, to the point of the switch. The point of the switch is the tip end of the movable rail of the switch which is planed down to fit closely against the main rail. The number of a frog is equal to the quotient of the distance from P to the line AB divided by the length of the line AB.

Turn-outs.—Turn-outs are short sidings used on single-track roads to permit cars running in opposite directions to pass each other. The proper location of turn-outs is governed to a certain extent by topography. They can be readily located by drawing up a train diagram; see *Railways, Energy Requirements and Motor Capacity for*. To keep the number of turn-outs at a minimum the time intervals between cars (headway) should all be multiples of the shortest time interval. For accurate results the diagram should be carefully drawn to a scale large enough so that locations can be measured with an error not to exceed 200 feet for distance and one minute for time.

CONSTRUCTION OF PERMANENT WAY.—In the preparation of the roadbed for ballast, ties and track, it should be noted that rails settle more or less and allowance must be made for this when grading is in progress. The surface of the roadbed should be flat, from 14 to 20 feet wide for a single-track road, and from 9 to 10 feet wider for a double-track road, with a ditch at each side for drainage. On this the ballast of broken stone, gravel or cinders is laid varying from 6 to 12 inches thick under the ties. The ballast should ultimately be brought up level with the tops of the ties.

Ballast. — Broken stone is best but most expensive in first cost and maintenance. It is clean and dustless. Gravel is cheaper and very satisfactory from a maintenance standpoint. It is apt to be very dusty. Cinders are fairly satisfactory but are very dirty.

Ties.—Ties are of the following materials in the order named: Oaks, southern pine, Douglas fir, cedar, chestnut, cypress, western pine, tamarack, hemlock, redwood, lodge-pole pine and white pine; see article on *Timber*. The average cost is from 80 to 30 cents each. Treated ties cost 95 cents. With the rapidly increasing cost of ties, preservative treatment is becoming important. Creosoting is best. Zinc chloride treatment is satisfactory in arid regions only. The average life of an untreated tie is 5 years for hemlock, 7 to 12 years for white oak, and 15 years for cedar ties. Treated ties may last 30 years, but must be protected from mechanical injury by rails and spikes. For this purpose tie-plates and screw spikes should be used. Ties are spaced about 2 feet between centers.

Rails. — See article on *Rails, Track and Third.*

Grade Crossings. — On high-speed lines grade crossings should be avoided wherever practicable. It costs less to avoid them in the beginning than to eliminate them afterwards. To eliminate an existing grade crossing costs from $40,000 up unless the topography is unusually favorable.

COST OF PERMANENT WAY. — When tracks are laid in paved streets the railway usually has to pay for paving 18 inches of the street outside the rails. The total cost of such track, excluding overhead construction, and using 8- or 9-inch girder rails is about $5 per foot of single track. When the track is constructed with a light T-rail, as may be the case when laid on a private right of way or at the side of a street where there is no paving, the cost may be as low as $1 per foot, exclusive of ballast, bonding, and overhead construction. Ballast will cost from $1000 for cheap gravel to $3000 for thin rock, per mile of track. Thick rock ballasting as used on steam railroads may go as high as $5000 per mile.

Maintenance Costs. — Maintenance of way costs will depend largely on the character of the original construction and also upon the character and amount of traffic. On typical Massachusetts street and interurban railways maintenance of way expenses are reported as from $200 to over $500 per mile of track. $200 per mile is not sufficient to maintain the road and track in an adequate manner, but from $350 to $380 is probably a fair figure.

REACTANCE COILS OR REACTORS.—(*See also Alternating Currents; Inductance and Inductive Reactance.*) Coils designed particularly for the purpose of introducing reactance (*see Inductance and Inductive Reactance*) into a circuit, when connected therein, are called "reactance coils" or "reactors."

APPLICATIONS. — Reactance coils are used wherever (1) it is desired to produce a voltage drop in an a-c. circuit without producing a proportionate loss in power (*see Controllers*); (2) to introduce inductance into a circuit where a compounding effect is to be obtained by passing a leading current through the coils (*see Converters, Synchronous*); (3) in large power stations to limit the short-circuit current; and (4) as "choke coils" in connection with lightning arresters (*see Lightning Protectors*).

RATING OF REACTANCE COILS. — It has been common practice to rate a reactance coil in terms of the kv-a. absorbed by it when carrying such a current (of given frequency) as will produce a temperature rise of 40° C. above a 25° C. room temperature; see, however, the recent recommendations regarding rating in the article on *Standardization Rules*. Usually the resistance is negligible compared with the reactance, and under these conditions the kv-a. rating $= xI^2$.

Per cent Reactance. — A reactance coil having a reactance of x ohms is said to have a "per cent reactance" equal to $(100\,x\,I) \div V$, where I is the normal or full-load current through it and V the *total* normal voltage across the circuit in which it is placed; i.e., the percentage reactance is the percentage ratio of the reactance drop at normal current to the total voltage impressed on the circuit in which it is inserted. When the coil is to be inserted in one branch of a Y, the voltage V is the volts to neutral.

In the case of a three-phase generator, three-phase transformer or bank of transformers, or set of three single-phase reactance coils, the Y reactance, x, (*see Alternating Currents*) is related to the per cent reactance, p, by the formula

$$x = \frac{10\,pE^2}{(kv\text{-}a.)}, \tag{1}$$

where E is the *kilovolts* between phases (i.e., between the terminals of the Y) and $(kv\text{-}a.)$ stands for the total kilovolt-ampere rating of the three phases.

DESIGN OF IRON-CORE REACTANCES. — When a high inductance is required the coils are usually wound on an iron core, which usually contains an air gap, for the inductance of a coil on a completely closed iron core is by no means a constant, due to the variation of the permeability of the iron with the magnetizing current, and a straight-line relation between voltage and current does not hold. When a relatively low inductance is required the iron core may be omitted entirely. Reactance coils for use in connection with synchronous converters have an iron core.

In iron-core reactances the air gap is usually of such a length that practically all of the reluctance of the circuit is in the air gap. Hence in calculating the reactance of the coil the reluctance of the iron portion of the path may be neglected without materially affecting the results, provided normal magnetic densities exist in the iron (60,000 to 80,000 lines per square inch, maximum values). As the gap is made adjustable such errors as result from this approximation are allowed for by adjusting the gap afterwards.

The inductance L in henries and the reactance x in ohms are given approximately (neglecting effect of iron) by the equations

$$L = \frac{3.2\,S^2 A}{10^8\,l} \quad \text{and} \quad x = 2\pi f L, \tag{2}$$

where S = number of turns in coil; A = cross section of path in gap, in square inches; l = length of gap, in inches; f = frequency in cycles per second. This must, however, be checked to see that the magnetic density B is not too great at the maximum current to be used, thus, $B = (3.2 \times \sqrt{2}\, SI) \div l$, where I = the effective value of current; B = maximum value of flux density = 60,000 to 80,000 lines per sq. in.

The losses in such a coil are the core-loss in the iron and the RI^2 in the copper. See article on *Magnetic Properties of Materials* for the method of calculating the core-loss. The procedure in proportioning the various parts is similar to that employed in the design of transformers (q.v.).

POWER-LIMITING REACTANCES.* — (*See also Power Stations.*) In order to avoid the prohibitive expense of high-voltage insulation, power-limiting reactances are always designed to be installed in the low-tension circuits. From the standpoint of economy, this requirement prohibits the use of a magnetic core. When power-limiting reactances are installed at a distance greater than one-half their diameter from any iron or steel structure, no appreciable eddy current or hysteresis losses will be produced in such structures.

The inductance and reactance of the coils can be calculated from the formula for a short solenoid given in the article on *Inductance and Inductive Reactance.*

It is desirable to reduce the size of reactance coils as much as possible, and they are therefore now usually designed for a temperature rise of 70° C. As to the dielectric test, the A.I.E.E. rules recommend 2¼ times the line voltage plus 2000 for one minute, from conductor to ground.

Location of Reactance Coils. — As noted above the reactance coils may be inserted in the leads from the generator, between sections of the low-tension bus-bars, or in the low-tension leads of the transformers. Which one of these locations or combinations is preferable depends on a number of conditions. Modern water-wheel-driven generators are now designed for a very high inherent reactance and external power-limiting reactances are usually inserted between the bus-bar sections or in the low-tension transformer leads.

Reactances in Generator Leads. — With reactances in the generator leads the current flowing in the armature winding is limited, and this method therefore affords an excellent protection for the generator itself. An objection to generator reactances is the fact that a short-circuit on or near the bus-bars will cause a voltage drop on all the feeder circuits connected thereto.

Reactances between Bus-bar Sections. — With reactance inserted between the bus-bar sections the trouble is confined to the particular section on which short-circuit takes place. Bus-section reactances afford no protection to the generators connected to the bus to which the faulty line is connected, but they give added protection to the generators on the other sections.

Reactances in Low-tension Leads of Transformers. — Reactances in the low-tension leads of the transformer banks are of considerable value for protecting against short-circuits in the lines, where they, of course, mostly take place. They are, however, not of value if the short-circuit should occur on the low-tension bus or in the generators or in their leads. There is also a constant loss of power in the reactance coils when they are inserted in the transformer leads, as is also the case when they are installed in the generator leads. For large systems this may reach a considerable value and must not be ignored when the selection of reactances is made.

Calculation of Short-circuit Kilovolt-amperes. — The short-circuit current for any arrangement of reactances and for a short at any point can be found

* By D. B. Rushmore.

with sufficient accuracy by neglecting the resistances of the apparatus and connections and calculating the resultant reactance by applying successively the formulas for two reactances in series or in parallel, as the case may be. Note that the resultant reactance X_s of two reactances, x_1 and x_2 in series, and the resultant reactance X_p of two reactances, x_1 and x_2 in parallel, are respectively

$$X_s = x_1 + x_2,\ X_p = \frac{x_1 x_2}{x_1 + x_2} \qquad (3)$$

provided the resistances of the circuits are negligible. The reactances, x_1, x_2, etc., of the various circuits can be calculated from the percentage reactance by formula (1). Let X_r be the resultant reactance of all the circuits feeding into the short circuit, and let E be the kilovolt rating of the generators, then

$$\text{Total short-circuit kv-a.} = \frac{1000\,E^2}{X_r} \qquad (4)$$

For example, consider the case of four, 12,000 kv-a., three-phase, 11,000-volt generators feeding into a bus which is divided into two sections, A and B, with two generators feeding into each section, and one transmission line from each section, each line fed through a bank of transformers. A set of reactance coils, having 6 per cent reactance, connects the two bus sections. The inherent reactance of each transformer bank is 8 per cent, and the inherent reactance of each generator is 20 per cent. The reactance of each generator is then 2.0 ohms; of each transformer bank 0.4 ohm, and of each set of reactance coils 0.6 ohm. Let a short circuit occur between the three wires of the line connected to the bus section B. We then have $2.0/2 = 1.00$ ohm in series with 0.6 ohm, or a total of 1.6 ohms, which total is in parallel with the other two generators, i.e., in parallel with 1.0 ohm, giving a resultant reactance up to the transformer bank of 0.6 ohm; this is in series with the transformer bank, giving a final resultant reactance, $X_r = 0.6 + 0.4 = 1.0$ ohm. Hence the total kilovolt-amperes, from formula (4), is 121,000, or about 10 times the rating of each generator.

DIMENSIONS, WEIGHT AND COST.—Iron-core reactances with air gap occupy from 0.30 to 0.50 cubic feet per rated kv-a., weigh from 20 to 50 pounds per rated kv-a. and cost from $2.00 to $4.00 per rated kv-a., the first figure in each case applying to air-blast reactances and the latter figure to oil-cooled reactances. Power-limiting reactances occupy from 0.3 to 0.6 cubic feet per rated kv-a., weigh from 20 to 30 lbs. per rated kv-a. and cost from $4 to $12 per rated kv-a. The first figure in each case applies to reactances having a rating of approximately 500 kv-a. and the latter for ratings of approximately 50 kva-a. These figures apply to 60-cycle reactances and should be increased from 10 to 15 per cent for 25-cycle reactances.

[W. I. Slichter.]

RECTIFIERS. — (*See also Arc, Electric; Converters; Motor-Generators.*) The term rectifier is applied to any stationary apparatus or rotating commutator for transforming alternating into direct current, or vice versa. Three types of rectifiers are in commercial use, viz., the mercury-arc rectifier, the electrolytic rectifier and the rotating commutator driven by a synchronous motor, but only the first type is at present of much importance commercially.

MERCURY-ARC OR MERCURY-VAPOR RECTIFIER. — The operation of this rectifier depends upon the fact that a tube containing mercury vapor under a low pressure and having one electrode of mercury, and the other of some other conductor, offers a very high resistance to a current tending to flow through the tube from the mercury to the other electrode, but has a very low resistance to a current flowing in the opposite direction, provided the current is once started by forming an arc in the tube, e.g., by tilting the tube so that the mercury touches for an instant the other electrode. See article on *Arc, Electric*.

Application. — Mercury-arc rectifiers find their chief application as a means of charging storage batteries and supplying a certain series type of d-c. arc lamp (*see Lamps, Electric*) from an a-c. supply. In the latter case the rectifier receives its current from a constant-current transformer and delivers a direct current of constant value. Mercury-arc rectifiers have also been tried out experimentally on electric cars and locomotives, power being supplied to the car or locomotive from a high-voltage a-c. trolley, stepped down to a lower voltage by transformers and converted into low-voltage direct current by means of the rectifiers. Although this scheme has not yet proved satisfactory commercially, it seems to be particularly promising when used in connection with high voltage (1200-volt) railway motors. The difficulty lies chiefly in producing a tube of rugged and lasting qualities.

Connections for Single-phase Operation. — The connections employed in practice are shown in Fig. 1. The complete equipment consists of a source of alternating current *HG*, the rectifier tube *AA'*, two reactances *E* and *F* and the load represented as a storage battery *J*. The rectifier tube is an exhausted glass vessel in which are two graphite electrodes (anodes *AA'*) and one mercury cathode *B*. Each anode is connected to a separate side of the a-c. supply, and also through one-half of the main reactance to the negative side of the load. The cathode *B* is connected to the positive side. There is also a small starting electrode *C* connected to one side of the a-c. circuit through a resistance and used for starting the arc. When the rectifier tube is rocked so as to form and break a bridge of mercury between the cathode *B* and starting anode *C* a small arc is formed. This produces mercury vapor in the tube and the arc immediately jumps to one or the other of the main anodes and alternates on these during regular operation.

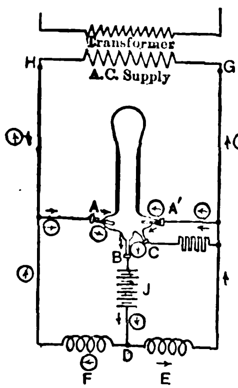

Fig. 1. Mercury-vapor Rectifier

Mode of Operation. — To analyze the operation, assume an instant when the terminal *G* is positive and *H* negative. The positive current will then flow from anode *A'* to cathode *B*, through the load *J* to *D* and through reactance *F* back to *H*. The current cannot jump from *A'* to *A* on account of the high

counter electromotive force of the arc. The small arrows surrounded by circles show the path of the current during this half cycle. During the next half cycle the terminal H is positive and the current flows to A through the tube to B, through the load J, reactance E and back to G. The small arrows show the path of the current during this half cycle. Hence during a whole cycle the cathode B is continuously negative but first one anode is active and then the other. If the voltage and current should become zero coincidentally the arc would become extinguished and operation cease. Hence the reactances E and F are introduced. At the end of the first half cycle described, when the line voltage drops to zero, the inductance of F maintains the current and a local circuit is formed through A, B and F, which maintains the arc until the voltage at G has risen to a value which will maintain the arc.

The rectifier thus makes use of both half waves, or the entire alternating current, and the result is a uniform pulsating uni-directional current. On account of the reactance in the circuit, this current in the load never falls to zero and, in fact, with sufficient reactance, may be made very nearly constant. But this extreme is not always desirable, as it distorts the current wave in the a-c. supply circuit.

Arc Rectifiers on Polyphase Circuits. — Rectifiers may be arranged on two-phase and three-phase circuits, and in fact there is an advantage in the arrangement of the reactances in these cases.

Efficiency of Mercury-arc Rectifier. — The losses in the rectifier correspond to a constant counter e.m.f. of about 14 or 15 volts, thus the efficiency of the tube is constant at all loads and at high voltages is very high; the higher the voltage the higher the efficiency. In fact, for high voltages the losses in the transformer and reactance coils form the major part of the total losses. On account of the small losses in the tube itself, there is very little heat to be dissipated, and rectifier tubes of large capacity are very small in bulk.

Kilowatt Capacity of Mercury-arc Rectifier. — Rectifiers have been built for voltages up to 6000. The tubes may be of glass or steel. The glass tubes have a capacity of about 40 amperes and the steel tubes from 200 to 300 amperes. Several rectifiers may be operated in parallel for large currents. The power factor of the combination of tube and controlling devices is about 90 per cent. Rectifiers have been built of a capacity sufficient to operate motor cars and locomotives.

Dimensions, Weights and Costs of Mercury-arc Rectifier Outfits. — A standard outfit consisting of rectifier tube, transformer, reactance, switchboard panel, switches and instruments to supply a load of 30 amperes at 110 volts d.c. would occupy a floor space 16×19 in., have a height of about 64 in., and weigh complete about 600 pounds. The first cost of the outfit would be between $200 and $250 and the cost of renewing the tube about $20. The net efficiency would be about 78 per cent. Such an equipment is frequently used for charging the batteries of electric vehicles from a-c. supply circuits.

ELECTROLYTIC RECTIFIERS. — (*See also Condensers; Lightning Protectors.*) The operation of this type of rectifier is in a general way the same as that of the mercury-arc rectifier, being based on the fact that a certain electrolytic cell having electrodes of different metals (e.g., aluminum and steel electrodes in a solution of ammonium phosphate) have the property of allowing a current to pass in only one direction. By suitably combining two of these cells both the half waves of an alternating current may be rectified. Such rectifiers have a low efficiency and due to the large losses in them heat very rapidly. They are therefore applicable only to the rectification of small currents. Examples are the electrolytic rectifier of Nodon described at the International Electric Congress of 1904.

MECHANICAL RECTIFIERS. — These usually consist of a commutator driven by a synchronous motor. Each commutator has as many live segments as there are poles on the synchronous motor. Alternate segments are connected to the source of alternating currents, and brushes properly spaced and bearing on the commutator collect the direct current. The objections to these devices are that if there is much inductance in the d-c. circuit (e.g., a motor) there will be a great deal of sparking, or if the load has a constant counter e.m.f. (e.g., a storage battery) there will be sparking. By alternating live and dead segments, this trouble can be obviated, provided the current to be rectified is not too large and the proportions of the live and dead segments are properly chosen. Commutator rectifiers of this type capable of rectifying currents up to 50 amperes at 200 volts have been constructed. The principal losses are in the driving motor; the efficiency is poor at light loads.

Many attempts have been made to produce a satisfactory rectifier by various schemes for interchanging the connections to the a-c. circuit at the end of every half wave, but none of them have as yet proved satisfactory for rectifying currents of any considerable magnitude. The difficulty lies chiefly in providing a means of preventing the formation of a spark when the circuit is interrupted or commutated.

[W. I. Slichter.]

REGULATORS. — (*See also Batteries, Storage, Applications of; Controllers; Rheostats; Starters, Motor; Switchgear Equipment for Power Stations.*) Devices for adjusting and controlling the voltage in an electric circuit are called regulators. They may be divided into two classes, depending on whether they operate directly on the circuit or indirectly by means of the excitation of the generator.

FEEDER OR POTENTIAL REGULATORS, as the name implies, operate to raise or lower the feeder voltage. Where a feeder circuit is operated from a constant potential bus and it is desirable to compensate for the drop in the feeder, there is usually installed a regulator which adjusts the voltage impressed upon the feeder so as to maintain proper voltage at the point of distribution.

With d-c. circuits the only way to raise the voltage of the feeder above that of the bus is to connect a booster or a storage battery (q.v.) in series. The feeder voltage may be lowered by connecting in resistance. Owing to the inefficiency of resistance control and the complication of providing boosters or batteries, feeder control of d-c. circuits is used only in special cases, such as for the distribution system of a direct-current railway.

Feeder control for a-c. circuits is accomplished by transformer action. Feeder regulation for such circuits can be made in various ways, the most common being the "induction" type and the "step" type.

Induction Regulators, also called "induction potential regulators," are used on either single-phase or three-phase circuits and are arranged for hand operation, motor operation with distant control, or for full automatic operation by means of relays. An induction regulator is a special type of transformer, built like an induction motor (q.v.) with a coil-wound secondary. The primary is permanently connected across the feeder circuit, and the secondary which is connected in series with the feeder is normally stationary, but is movable at will for the purpose of adjusting the voltage. In comparison with the step-type regulator (*see below*) the induction regulator possesses the advantage of being operated without short-circuiting any transformer coils. It has the disadvantages of a large magnetic leakage and a high value of exciting current.

Single-phase Induction Regulator. — This regulator has a secondary induced voltage whose value depends on the relative angular position of the primary and secondary coils, but which is always in time phase with the primary voltage. This induced voltage is a maximum when the axes of the coils coincide and it is zero when the coils are at right angles to one another. The resultant feeder voltage is equal to the arithmetical sum (or difference) of the primary and secondary voltages.

Polyphase Induction Regulator. — This regulator has a rotating flux of constant value, set up by the primary current. Thus the secondary induced voltage is also constant in value but differs in phase from the normal line voltage depending on the angular relation between the primary and secondary windings. The resultant delivered voltage is the vector sum of the primary and secondary voltages, and its value varies with the position of the movable member.

Step-type Regulators, also called "contact-voltage regulators," consist essentially of a stationary transformer provided with a large number of secondary taps for cutting in and out sections of the transformer windings. The taps are connected with a dial or drum so that any pair of taps can be connected to the feeder circuit according to the voltage required.

The moving arm on the dial-type regulator is usually arranged so that in passing from the position of maximum boost the number of secondary turns in series with the circuit is reduced in equal steps until the turns are all cut out. Further rotation in the same direction throws over the reversing switch and

then cuts in the same secondary turns in opposition to the main voltage until the position of maximum bucking is reached, when a stop prevents any further rotation in that direction. A similar stop prevents overtravel in the position of the maximum boost.

Automatic Operation of Feeder Regulators with either single- or three-phase circuits is obtained by the action of a voltage relay, which may or may not have a compensating device. This relay acts in conjunction with the motor on the regulator so that, as the load comes on or as the bus-voltage drops, the motor will turn the regulator in such a direction as to increase the voltage. By means of a compensator which can be set for a certain resistance and a certain inductive drop, the voltage at the point of distribution can be maintained constant independent of the amount and power factor of the load, provided the total drop is within the range of the regulator.

FIELD REGULATORS. — In order to maintain practically-constant voltage on a-c. and d-c. generators, or to have these machines compound automatically to take care of feeder drop, field regulators of either non-automatic or automatic types are employed. The former are hand-controlled field rheostats (*see Rheostats*). The latter are made in various forms, of which the Tirrill regulator is the best known in America.

Tirrill Regulator. — This regulator depends for its operation upon the rapid opening and closing of a circuit that shunts the field rheostat, and thus changes the resistance in the field circuit of the generator to be regulated. For d-c. service the regulator usually works upon the main generator field and for a-c. service upon the field of the exciter. In both cases the rheostat is so adjusted that when in circuit it tends to lower the voltage considerably below normal, and when the rheostat is short-circuited the generator voltage rises. The regulator automatically closes the shunt circuit when the voltage drops to a predetermined value and opens the shunt circuit when the voltage rises above that value.

The main features of the Tirrill regulator and those which have been so conducive to its successful operation are: (1) the method of control by shunting the rheostat and (2) the fact that with the total range of regulation from no load to full load the maximum travel of the only moving parts, the vibrating contacts, is only 1/32 inch. The vibrations are so rapid that the time factor is reduced to a minimum and there are no retarding effects due to dash pots or other damping devices.

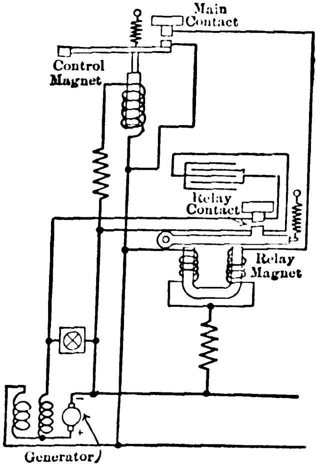

Fig. 1. Connections for Direct-current Tirrill Regulator

Tirrill Regulator for Direct-current Generator (Fig. 1). — This consists essentially of a main control magnet whose winding is connected across the generator terminals, and a differentially-wound relay magnet. When the effect of the potential winding increases, due to a rise in the generator voltage, the contact of the main control magnet is opened and in turn one winding of the relay magnet is deënergized. Thus the relay contact is opened and the short-circuit removed from the generator rheostat. When the generator volt-

age drops, the main contact is closed and the differentially-wound relay magnet acts to short-circuit the field rheostat. The relay contacts are shunted by a condenser to reduce sparking.

In case the generator is to overcompound for line drop a current winding is added to the main control magnet and is connected across a shunt in one of the local mains. The action of this current winding opposes the action of the potential winding in the control magnet end, and thus makes the generator overcompound for line drop. Regulators of this type can be adjusted for a line drop up to 15 per cent.

Where the generators are shunt wound a separate regulator is required for each machine which is operating at any time. Where several small compound machines are operating in parallel and all of the regulating is done by one machine, the others trailing after, provision is made for connecting any machine to the regulator. For field currents in excess of about 3 amperes at 250 volts, it is found that one relay contact is not sufficient, and for such cases regulators are built with as many as 10 relays, all being operated by a single main control magnet. For still larger d-c. generators whose field current could not be handled by a multiple-contact regulator, it is necessary to supply a separate exciter or exciters and the regulator then controls the field circuit of the exciter as described below for a-c. generators.

Tirrill Regulator for Alternating-current Generator (Fig. 2).—This works on the exciter field. The main contacts with this type of regulator are acted on by two sets of control magnets, one connected across the exciter bus

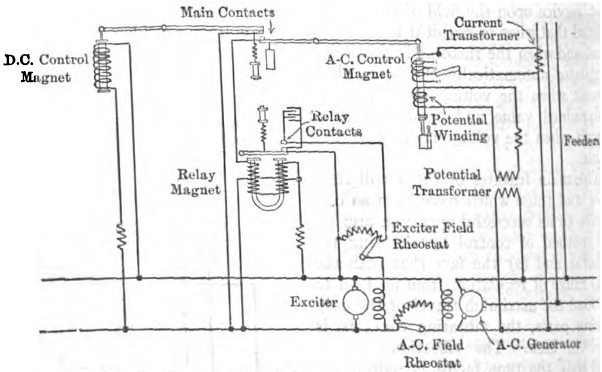

Fig. 2. Connections for Alternating-current Tirrill Regulator

and tending to move the main contacts further apart as the exciter voltage rises, and the other acted upon by a-c. potential and current coils. Suitable springs and counterweights allow the proper adjustment to be made. When the main contact closes it energizes the relay magnet, thus closing the relay contact, short-circuiting the exciter rheostat and raising the exciter voltage and consequently the generator voltage. The use of the exciter voltage as one of the main control circuits prevents the generator voltage "overshooting," for as the exciter voltage rises to bring up the a-c. voltage the d-c. control tends to keep the main contacts apart and so reduce the voltage again.

The compensating current winding of the a-c. solenoid is provided with a dial switch to give any amount of compensation required for the feeder circuit in which the current transformer is located. Where it is desired to compensate

for both resistance and inductive drop under varying power factors a special compensator is provided. A modification of the regulator to take care of the large exciters has a number of relay contacts all operated at the same time from the one set of control contacts, the various relays being shunted by condensers to reduce the sparking. A single regulator may serve a number of alternators if they are operated in parallel and if all use the same exciter. If two or more exciters are operated in multiple, a single regulator will suffice; if not operated in multiple, a separate regulator must be installed for each exciter.

REGULATORS, STORAGE BATTERY. — See articles on *Batteries, Storage*.

COSTS. — Tirrill regulators for d-c. service are built for pressures up to 550 volts and for controlling a total excitation current up to 30 amperes at 250 volts. The regulators for use with exciters are built for machines with a range of 2 to 1 from no-load to full-load excitation current. For a-c. service Tirrill regulators are built for controlling a total excitation current of 96 amperes with a range of 2 to 1 from no-load to full-load excitation current. The cost of both d-c. and a-c. types varies considerably according to the character of the installation, but for rough preliminary estimates may be taken as ranging from $230 for a total excitation current of 2.5 amperes at 250 volts to $910 for a total excitation current of 55 amperes at 250 volts.

[S. Q. HAYES.]

RELAYS. — (*See also Circuit Breakers; Telegraphy; Telephony; Regulators; Signaling, Railway.*) A relay is a device which opens or closes a local circuit under predetermined electrical conditions of the main circuit. There are three general classes of relays as determined by their respective functions of (1) protecting the main circuit, (2) regulating the current in the main circuit, or (3) signaling the condition of the main circuit.

PROTECTIVE RELAYS are auxiliary devices supplied for use with circuit breakers on systems that require protection more selective and flexible than that afforded by the usual control features of automatic circuit breakers (q.v.). The closing of a local circuit through the action of the relay causes in turn the tripping of the circuit breaker.

Types of Protective Relays. — The types which are most commonly employed are given in the following table, together with the apparatus with which each type is applied and the protection furnished by the operation of the relay.

Relays are built to furnish protection against overvoltage, no voltage, overload, no load, reverse load and reverse phase. They may operate either directly or in connection with other relays, and may be made instantaneous or provided with a time limit either of definite duration (time-limit relay) or inversely proportional to the extent of overload (inverse-time-limit relay).

TYPES OF RELAYS

Type of Relay	Application	Operations	Approximate cost per relay*
D-C. overvoltage	Storage batteries d-c. apparatus	Prevents overcharging Prevents damage from excess voltage	$13.00
D-C. reverse current	Storage batteries rotary converters	Prevents discharging into charging source Protects against reversal of flow of energy	43.00
D-C. low-voltage release	D-C. motors	Operates if voltage falls below given value	13.00
D-C. underload	Storage batteries	Disconnects on completion of charge	13.00
A-C. overload	Feeders, motors, rotary converters, transformers	Protects against overload	14.50
A-C. overload and reverse load	Feeders, generators	Protects against overload and reversal of flow of energy	32.50
A-C. low-voltage	Induction motors	Protects against fall in line voltage	14.50
A-C. reverse phase	Synchronous apparatus	Protects against reversal of phase progression	32.50

* Costs do not include shunts for d-c. relays or current and potential transformers for a-c. relays, as the cost of these varies greatly with current and voltage.

Definite Time-limit Relays are used with circuits where the service must be maintained at all hazards no matter how great is the overload, provided it does not last more than a definite period of time, say from two to eight seconds. The allowable length of this time depends on the ability of the system to withstand such conditions; also on the length of time required for various feeder breakers to trip out and thus relieve the system protected by the breaker with definite time limit.

Inverse Time-limit Relay gives a selective action, whereby the time of operation varies inversely with the load. With this type of relay the faulty line carrying the heavier load usually will have its breaker tripped out before the other breakers are affected.

Example of Use of Relays. — The various types of relays that may be used to advantage in a system are shown diagrammatically in Fig. 1, where

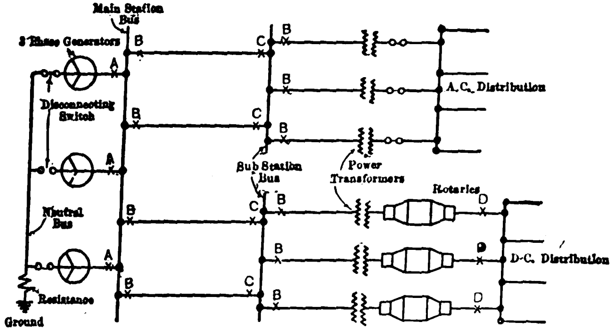

Fig. 1. Diagram Illustrating Use of Various Types of Relays

three a-c. generators operate in parallel with their neutral points grounded through a resistance and feed a common bus supplying current to power transformers, rotaries, etc., for a-c. and d-c. distribution. Relays for the operation of circuit breakers are inserted as follows:

At A — a-c. overload and reverse load relays.
B — a-c. overload time-limit relays.
C — a-c. reverse load, time-limit relays.
D — d-c. reverse current, inverse time-limit relays.

Principle of Operation of a protective relay depends somewhat on the duty to be performed. The actuating mechanism usually involves such a motive device as a solenoid and core, or a rotating motor. The mechanisms described below are those most frequently used for the respective types of service.

D-C. Overvoltage Relay. — One design consists of a permanent magnet which forms a base and two iron cores mounted parallel to the base and attached to it at one end with an eccentrically-pivoted armature carrying a suitable contact. With no current flowing the two cores exert an equal pull (due to the magnetic field of the permanent magnet) on the pivoted armature, which, due to its eccentric mounting, is pulled up against one core. When voltage is impressed on the coils wound on the iron cores the magnetism in one pole is strengthened and in the other weakened. At the predetermined overvoltage the position of the armature is reversed, notwithstanding its eccentric mounting, and the contact is closed, tripping the breaker.

D-C. Reverse-current Relays for instantaneous operation are similar in construction to overvoltage relays (*see preceding paragraph*). The solenoids

however, are operated from a shunt in such a way that with the current in the normal direction the contact is held open, but when the current reverses in direction the contact is closed, thus tripping the breaker.

Reverse-current Time-limit Relays are built on the principle of a permanent-magnet d-c. ammeter operated from a shunt. In normal operation the armature of the relay tends to turn in one direction but is restrained by a stop; in the case of current reversal the armature turns in the opposite direction, its rate of movement being proportional to the strength of the current. The angle through which the armature has to turn to close the contacts is adjustable by moving the stationary contact.

A-C. Overload Relays are usually built in single-phase units and for either instantaneous, definite time-limit, or inverse time-limit operation. The relay consists essentially of a solenoid and core. In the instantaneous relay the core lifts immediately upon occurrence of overload and closes or opens the circuit-breaker contacts when the current in the coil reaches a certain value. With the inverse time-limit relay the movement of the core is retarded by a bellows which has an adjustable valve and which is mounted above the coil. With the definite time-limit relay the same kind of bellows and valve is used but the solenoid does not work directly on the bellows. When the overload occurs the core rises instantly, compressing a spring which in turn acts on the bellows. If the core, due to continued overload, keeps the spring in compression the required time, the air will be forced out of the bellows and the tripping circuit operated. Relays of this type are usually operated from current transformers, but are sometimes mounted on a high-tension insulator and connected in the high-voltage circuit.

A-C. Reverse-load Relays are usually made of the wattmeter type with moving contacts adjustable to trip the breaker at any predetermined load in the reverse direction. They are made so as to have practically the same torque at low power factor as at high, and to be operative when the voltage drops almost to zero.

Relay Switch. — Where, as frequently happens, the tripping contacts of a relay will not carry enough current to trip the circuit breaker, a relay switch is employed. In this case the relay merely energizes the operating coil of the relay switch whose contacts can be made suitable for any reasonable amount of current.

Rating of Protective Relays for overload service is given usually in terms of maximum current in the main circuit (secondary of transformer with a-c.). For reverse-load relays the rating is expressed as the percentage of reverse load on which they will operate. For relays which are not instantaneous in their action a time rating in seconds is usually given.

REGULATING RELAYS. — See article on *Regulators*.

SIGNALING RELAYS. — See articles on *Telegraphy; Telephony; Signaling, Railway*.

COSTS. — See table above.

[S. Q. HAYES.]

RESISTANCE AND CONDUCTANCE, ELECTRIC. — (*See also Alternating Currents; Bridges for Electrical Measurements; Electricity and Magnetism, Principles of; Resistors, Standard; Skin Effect; Wires and Cables; Wires, Resistor.*) The general definition of the resistance R' of a substance between any two equipotential surfaces intersecting the path of a current I is

$$R' = \frac{P_h}{I^2}, \tag{1}$$

where P_h is the power dissipated as heat between the two equipotential surfaces and I is the *effective* value of the *total* current from one surface to the other. In the case of a varying current this dissipation of heat may occur in four different ways, viz., (1) as heat due to the conduction current through the substance, (2) as heat due to dielectric hysteresis accompanying the displacement current through the substance (when the latter is an insulator), (3) as heat due to magnetic hysteresis accompanying the varying magnetic flux produced by the current and (4) as heat due to eddy currents induced in neighboring conductors.

In the case of a continuous (non-varying) current the last three effects do not occur, and the heat is that due to the conduction current only. The resistance offered by a substance to a continuous current is called the "true," "ohmic," "continuous-current" or "direct-current" resistance, as distinguished from the "effective" resistance offered by the substance to a varying current. The effective resistance, even when there are no losses due to dielectric or magnetic hysteresis, is in general greater than the ohmic resistance, due to the skin effect; see *Skin Effect*.

Similarly, the general definition of conductance is

$$G' = \frac{P_h}{V^2}, \tag{2}$$

where P_h has the same meaning as above and V is the *effective* value of the potential difference between the two equipotential surfaces. When the voltage is non-varying the conductance is called the "true," "ohmic," "continuous-current" or "direct-current" conductance as distinguished from the "effective" conductance to a varying current.

In the case of a *continuous*, or constant current I, the above expressions for resistance and conductance reduce to

$$R = \frac{V}{I}, \qquad \text{and} \qquad G = \frac{I}{V}, \tag{3}$$

provided there is no source of e.m.f. between these two surfaces. The ohmic resistance and conductance, given by equations (3), are reciprocals of each other, but this is not true for the effective resistance and conductance.

RESISTIVITY AND CONDUCTIVITY. — When the current stream lines from one equipotential surface to the other are straight and parallel and uniformly distributed, and l is the distance between the two surfaces and A the area of each, the ohmic resistance and conductance of the prism or cylinder of the substance thus formed are respectively

$$R = \rho\frac{l}{A}, \text{ and } G = \gamma\frac{A}{l}, \tag{4}$$

where ρ and γ (which are reciprocals) are called the resistivity* and conductivity* of the substance respectively. For a given material at constant temperature throughout ρ and γ are constants.

* Also called specific resistance and specific conductance.

Units of Resistivity and Conductivity. — From (4) it is evident that ρ is the resistance of a cube of the substance of unit length on each edge when the current stream lines are uniformly distributed and parallel to four of the edges of the cube; similarly, γ is the conductivity of such a unit cube. Resistivity is therefore frequently expressed as ohms or microhms per centimeter cube or per inch cube, and conductivity as mhos or mega-mhos per centimeter or inch cube. Note that a resistivity of x microhms per centimeter (or inch) cube is equivalent to a conductivity of $\frac{1}{x}$ mega-mhos per centimeter (or inch) cube.

Ohms per Mil-foot. — It is frequently convenient in dealing with wires to express lengths in feet and cross sections in circular mils. The corresponding value of the resistivity ρ is then expressed in ohms per mil foot.

Ohms per Meter-gram. — The cross section of a bar or wire of uniform cross-section is equal to the volume of the bar divided by its length, and the volume of the bar is in turn equal to its mass divided by the density of the material of which it is made. Hence, using the same symbols as above, and in addition calling m the mass of the conductor and δ its specific gravity,

$$R = \rho\delta \frac{l^2}{m}. \tag{5}$$

For a given material at a given temperature $\rho\delta$ is also constant, hence

$$R = k\frac{l^2}{m}, \tag{5a}$$

where k is a constant (equal to $\rho\delta$) for a given material at a given temperature; this factor k is then called the specific resistance of the conductor in "ohms per meter-gram" when l is in meters and m in grams.

Pounds per Mile-ohm. — In telephone and telegraph practice the specific resistance of a conductor is also expressed as the weight w, in pounds, of a wire one mile long having a resistance of one ohm. This weight w is sometimes called the "mile-ohm equivalent" of the wire.

"Annealed Copper Standard." — Matthiessen's Standard. — In 1862 Matthiessen published the results of a number of determinations of the resistivity of copper. Recent determinations of the conductivity of a number of samples of commercial annealed copper wire at the Bureau of Standards (*Bull. Bur. Stand., 1911, Vol. 7, p. 103*) gave a mean value of the resistivity very close to Matthiessen's value. A conductivity corresponding to 0.15328 ohm per meter-gram at 20° C. has been adopted (1912) by the Bureau and by the American Institute of Electrical Engineers (1914)* as the "standard" of conductivity, the name "Annealed Copper Standard" being suggested for it. (*See Standardization Rules of the A.I.E.E.*) Matthiessen's Standard, formerly used by the American Institute of Electrical Engineers as the basis for their wire tables corresponded to 0.141729 ohm per meter-gram at 0° C.

To reduce the value of the Annealed Copper Standard to resistivity and conductivity in volume units the value of 8.89 has been adopted as the density of copper in grams per cubic centimeter at 20° C. which corresponds to 8.90 grams per cubic centimeter at 0°C.

Per cent Conductivity. — The Bureau of Standards recommends that whenever the conductivity of a sample is expressed as a percentage, the measured resistivity or conductivity be corrected to reduce it to the value it would have

* Also adopted by the national electrical engineering societies in Germany and France.

at 20° C.; see section on *Temperature Coefficient of Resistance*, below. A conductivity of P per cent is equivalent to

$15.328 \div P$ ohms per meter-gram at 20° C.
$172.41 \div P$ microhms per centimeter cube at 20° C.
$67.87 \div P$ microhms per inch cube at 20° C.
$1037.1 \div P$ ohms per mil-foot at 20° C.

For example, a conductivity of 60 per cent is equivalent to a resistance of 17.285 ohms per mil-foot.

CALCULATION OF THE OHMIC RESISTANCE OF A CONDUCTOR. — Values of the resistivity of various materials are given in the table below. Experiment shows that the resistance of a given length of wire of uniform cross section is independent of the shape into which the wire is bent, provided the diameter of the wire is small compared to the radius of curvature of the curve into which it may be bent. This condition is almost always realized in practice, and consequently formulas (4) and (5a) are in general directly applicable to the calculation of the resistance of a wire whether the wire be straight or curved or wound into a coil of any shape. These formulas are also applicable to the calculation of the resistance of a rod or bar, provided the rod or bar is not bent into a sharp curve, and the distance between its points of connection to the circuit is large compared to the linear dimensions of its cross section. Care should be taken, however, to express all quantities in the proper units; for example, the resistance in *ohms* of a wire which has a specific resistance of 1.6 microhms per centimeter cube, a length of 1000 feet and a cross section of ¼ square inch, is

$$R = 1.6 \times 10^{-6} \frac{1000 \times 12 \times 2.54}{0.25 \times (2.54)^2} = 0.0302 \text{ ohm}.$$

Resistance Formulas When the Stream Lines are Not Parallel and Uniformly Distributed. — When the stream lines of the current are not all of the same length, as, for example, when a current is established in a heavy short bar bent into a sharp curve, the resistance of the bar can be calculated only when the distribution of these stream lines is known. Again, when the stream lines of the current are not parallel, e.g., the leakage current through the insulation of a cable, these formulas are not applicable. However, when the formula for the capacity between any two conductors is known (*see Capacity and Charging Current*), the resistance of the insulation, if uniform throughout, may be found by multiplying the *reciprocal* of the capacity, viz., $\frac{1}{C}$, by $\frac{K\rho}{4\pi}$, where ρ is the resistivity of the insulation and K the specific inductive capacity in the capacity formula. See articles on *Rheostats* and *Wires and Cables, Insulated.*

TEMPERATURE COEFFICIENT OF ELECTRIC RESISTANCE. — The resistance temperature coefficient β_t of a substance *at* any temperature t is defined as the rate of change of the resistance at this temperature, viz. $\left(\frac{dR}{dt}\right)_t$, divided by the resistance R_t at this temperature, i.e.,

$$\beta_t = \frac{1}{R_t}\left(\frac{dR}{dt}\right)_t. \tag{6}$$

The *mean* temperature coefficient α_t between any two temperatures t and t_1 *referred to* the temperature t is defined as the *average* change in the resistance in this interval per degree change of temperature, viz.,

$$\alpha_t = \frac{R_{t_1} - R_t}{R_t\,(t_1 - t)}. \tag{7}$$

General Expression for Change of Resistance with Temperature.—In general, the relation between the resistance R_t of a given mass of a substance at any temperature t may be expressed in terms of its resistance R_0 at zero degrees as follows:

$$R_t = R_0 (1 + at + bt^2 + \ldots), \tag{8}$$

where a, b, etc., are constant coefficients.

Linear Relation Between Resistance and Temperature.—When all the coefficients except the first one, a, are of negligible magnitude, i.e., when the relation between the resistance and temperature is a *linear* one, then, from the above definitions, the *mean* temperature coefficient (α_t) referred to a given temperature t is equal to the temperature coefficient (β_t) *at* that temperature, and the zero degree temperature coefficient α_0 ($= \beta_0 = a$) and the t' degree temperature coefficient $\alpha_{t'}$ are related as follows:

$$\alpha_{t'} = \frac{\alpha_0}{1 + \alpha_0 t'}, \tag{9}$$

and

$$R_t = R_0 (1 + \alpha_0 t) = R_{t'} [1 + \alpha_{t'} (t - t')], \tag{10}$$

where R_0 is the resistance at zero degrees, $R_{t'}$ the resistance at t' degrees and R_t the resistance at t degrees.

For most metals the simple linear relation expressed by equation (10) represents the experimental facts within practical limits of accuracy and for ordinary temperature ranges; values of α_0 are given in the table below. For dielectrics, however, the relation between the resistance and temperature is by no means linear, and several terms in such an expression as equation (8) are needed to represent the facts; see *Insulating Materials, Properties of*, particularly the subheadings *Cambric, Paper and Rubber.*

Calculation of Change in Resistance With Temperature.—Equation (10) may be conveniently expressed in the form

$$\frac{R_{t'}}{R_t} = \frac{T_0 + t'}{T_0 + t}, \tag{11}$$

where T_0 is written for the reciprocal of α_0, viz., $T_0 = \dfrac{1}{\alpha_0}$. (11a)

Equation (11) will be found very convenient for calculating the change of resistance with temperature and the change of temperature corresponding to two measured resistances, particularly when a slide rule is used.

T_0 is approximately equal to the number expressing the absolute zero on the mercury thermometer scale (except for magnetic metals) and is sometimes called the "inferred absolute zero" for the particular metal in question.

MEASUREMENT OF RESISTANCE, RESISTIVITY AND TEMPERATURE COEFFICIENT.—The simplest method of measuring a resistance in ordinary engineering work is to send a direct current through the conductor and measure this current by means of an ammeter (q.v.) and measure the potential difference across it by means of a voltmeter (q.v.). For measuring very low resistances, however, and for high-precision measurements, a bridge method should be used; see *Bridges for Electrical Measurements.*

VALUES OF RESISTIVITY AND TEMPERATURE COEFFICIENT.—The resistivity and temperature coefficient of the more common metals and alloys are given in the table below.

RESISTIVITY AND TEMPERATURE COEFFICIENT OF RESISTANCE*

1 microhm per centimeter cube $= \frac{1}{2.5400}$ microhms per inch cube
= 6.0153 ohms per mil-foot
= 0.01 δ ohms per meter-gram, where δ is the specific gravity.
= 57.08 δ pounds per mile-ohm.

ρ microhms per cm. cube at 20° C. $= \frac{172.4}{\rho}$ per cent conductivity at 20° C.

The zero degree Fahrenheit temperature coefficient is equal to

$$\frac{5\alpha_0}{9 - 160\alpha_0}.$$

(5) Thomas Prosser and Son. (6) Dr. Frink, Trans. Am. Electro-chem. Soc.. 1910, Vol. 17. (7) *Copper Wire Tables*, Circ. No. 31, Bureau of Standards, 1914. (8) Electrical Alloy Co.

Resistivity and Temperature Coefficient of Some Common Solutions. — (*See also Electrochemistry, Principles of.*) The table on p. 1226 is based on data given by Kohlrausch and Holborn (*Leitvermögen der Elektrolyte, Leipsig,* 1898). The temperature coefficient given is that corresponding to an increase of temperature from 18° C. to 19° C., and is a negative quantity, i.e., for an increase of temperature the resistance decreases. The resistivity temperature coefficient of aqueous solutions diminishes rapidly with increase of temperature, i.e., the higher the temperature the less is the decrease in resistance for each degree increase in temperature.

Resistivity and Temperature Coefficient of Ordinary Water. — The resistivity of ordinary tap or river water ranges from 1200 to 12,000 ohms per centimeter cube, ordinarily being between the limits 2000 and 5000 ohms per centimeter cube. The change of the resistance of such water with temperature between the limits 0° C. and 100° C. may be represented to a fair degree of approximation by the formula

$$R_t = \frac{40\, R_{20}}{20 + t},$$

where R_{20} is the resistance at 20° C. and t is any other temperature between 0° C. and 100° C. (*From Tests by Applequest and McKenny, Mass. Inst. of Tech.*, 1912.)

RESISTIVITY OF SOLUTIONS AND THEIR TEMPERATURE COEFFICIENT OF RESISTANCE

$$1 \text{ ohm per centimeter cube} = \frac{1}{2.540} \text{ ohm per inch cube.}$$

By per cent solution is meant the weight of the dissolved salt or acid expressed as a percentage of the weight of the solution.

For a dilution less than 5% the resistivity is approximately inversely as the per cent of dissolved salt or acid, i.e., a 2 per cent solution of common salt has a resistivity of approximately $14.9 \times 5/2 = 37$ ohms per centimeter cube. As noted above the resistivity of ordinary tap water ranges from 1200 to 12,000 ohms per centimeter cube; a solution made from such water can not of course have a resistivity greater than that of the water.

[H. PENDER and R. G. HUDSON.]

RESISTORS, STANDARD, AND RESISTANCE BOXES.— (*See also Bridges for Electrical Measurements; Resistance and Conductance; Wires, Resistance; Rheostats.*) The primary standard of resistance is a mercury column of certain specified dimensions (*see below*). Secondary or commercial standards are made in two forms, viz.: (1) resistance standards each consisting of a single coil, carefully calibrated, mounted in a metal case, and (2) the ordinary resistance box, which contains a group of coils of known resistance.

The ultimate or primary standard of resistance, when measured in the international units, is the resistance of a column of mercury at 0° C. having a length of 106.300 centimeters and having a mass of 14.4521 grams (*see Units, Practical Electrical*).

STANDARD MERCURY RESISTANCE. — For the practical realization of such a standard, the International Conference on Electrical Units held in London in 1908 adopted the following specifications:

The glass tubes used for mercury standards of resistance must be made of a glass such that the dimensions may remain as constant as possible. The tubes must be well annealed and straight. The bore must be as nearly as possible uniform and circular, and the area of cross-section of the bore must be approximately one square millimeter. The mercury must have a resistance of approximately one ohm.

Each of the tubes must be accurately calibrated. The correction to be applied, to allow for the area of the cross-section of the bore not being exactly the same at all parts of the tube, must not exceed 5 parts in 10,000.

The mercury filling the tube must be considered as bounded by plane surfaces placed in contact with the ends of the tube.

The length of the axis of the tube, the mass of mercury the tube contains and the electrical resistance of the mercury are to be determined at a temperature as near to 0° C. as possible. The measurements are to be corrected to 0° C.

For the purpose of the electrical measurements, end vessels carrying connections for the current and potential terminals are to be fitted on to the tube. These end vessels are to be spherical in shape (of a diameter of approximately four centimeters) and should have cylindrical pieces attached to make connections with the tubes. The outside edge of each end of the tube is to be coincident with the inner surface of the corresponding spherical end vessel. The leads which make contact with the mercury are to be of thin platinum wire fused into glass. The point of entry of the current lead and the end of the tube are to be at opposite ends of a diameter of the bulb; the potential lead is to be midway between these two points. All the leads must be so thin that no error in the resistance is introduced through conduction of heat to the mercury. The filling of the tube with mercury for the purpose of the resistance measurements must be carried out under the same conditions as the filling for the determination of the mass.

The resistance which has to be added to the resistance of the tube to allow for the effect of the end vessels is to be calculated by the formula

$$A = \frac{0.80}{1063\pi}\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \text{ohm},$$

where r_1 and r_2 are the radii in millimeters of the end sections of the bore of the tube.

The mean of the calculated resistances of at least five tubes shall be taken to determine the value of the unit of resistance.

For the purpose of the comparison of resistances with a mercury tube, the measurements shall be made with at least three separate fillings of the tube.

STANDARD SINGLE-COIL RESISTANCES. — The mercury standard resistance is cumbersome to work with and must be kept at constant zero temperature. Secondary standards, made of wire having a low temperature coefficient, are therefore universally employed in ordinary testing laboratories. The unit is provided with suitable heavy copper terminals so arranged that it may be hung from mercury cups and dipped into an oil bath. The object of the oil bath is to keep the temperature constant. Very low-resistance units, designed to carry large currents, are kept cool by means of water circulating in a coil of pipe within the case itself. Low-resistance units are also provided with "potential terminals," see Fig. 1, the stated resistance being the resistance between these terminals.

Reichsanstalt and N.B.S. Types. — There are at present two recognized types of resistance standards, the Reichsanstalt type and the National Bureau of Standards (or N. B. S.) type. Fig. 1 shows a 0.1-ohm standard of the first type, and Fig. 2 a 1-ohm standard of the N. B. S. type.

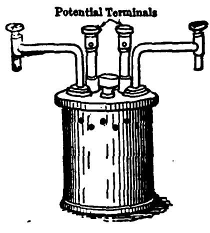

Fig. 1. Reichsanstalt Type Resistance Standard

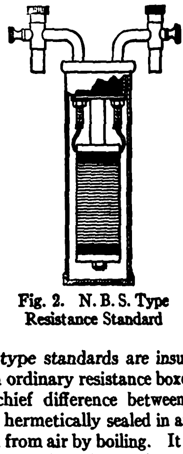

Fig. 2. N. B. S. Type Resistance Standard

The Reichsanstalt type and the N. B. S. type standards are insulated and baked in much the same manner as the coils in ordinary resistance boxes, though of course more carefully calibrated. The chief difference between the two types of standards is that the N. B. S. type is hermetically sealed in an oil-filled brass case, the oil having previously been freed from air by boiling. It is claimed that the N. B. S. units hold their calibration better than the Reichsanstalt units, the latter being subject to slight variations of resistance in climates where wide changes of humidity occur. (*See Bulletin Bureau of Standards, Vol. 5, p. 413.*)

Precision and Current-carrying Capacity of Standard Resistances. — The makers of standard units usually guarantee their accuracy as given below. The current-carrying capacity of the units is also given.

REICHSANSTALT TYPE, STANDARD RESISTANCE

Size of unit	Max. amp.	Error not greater than	Size of unit	Max. amp.	Error not greater than
0.0001	100	1/25 %	10	.3	1/100 %
0.001	30	1/25	100	.1	1/100
0.01	10	1/50	1,000	.03	1/100
0.1	3	1/50	10,000	.01	1/100
1	1	1/100	....	....	....

The National Bureau of Standards will calibrate any of these units and guarantee their accuracy of calibration to the above degree of precision, the charge being $4 to $6 per unit according to the value of the resistance.

RESISTANCE BOXES. — A brief description of the construction and arrangement of the coils in ordinary resistance boxes is given below.

Construction of Coils. — The coils are always wound non-inductively, that is, there are as many turns carrying the current in the right-handed direction as in the left-handed direction; this construction is illustrated in Fig. 3. Manganin wire (*see Wires, Resistor*) is usually employed. This wire is double-silk or enamel insulated, and is wound on wood or metal spools. Metal spools do not change in shape as wooden spools are liable to do, and since they more readily conduct the heat away, they may be safely used with larger currents.

The wound spools are then dipped in shellac and baked from 10 to 15 hours at a temperature of 140° C. This baking removes the tension from the wire due to the winding and the resistance is rendered constant, whereas coils not treated in this manner will change their resistance to some extent long after being wound. The resistance coils are adjusted to the desired values by varying the length of the wire, and copper terminals are silver soldered to the ends of the resistance wire. The coils are then ready for soldering in place in resistance boxes.

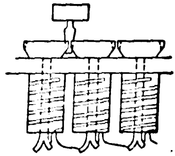

Fig. 3. Resistance Coil Construction

Arrangement of Coils. — The principal arrangements employed at the present time in the construction of resistance boxes are the 1, 2, 3, 4 plan, the 1, 2, 2, 5 plan and the decade plan.

The 1, 2, 3, 4 and the 1, 2, 2, 5 Plans. — Resistance boxes built on the 1, 2, 3, 4 plan have coils of the following resistances: 1, 2, 3, 4, 10, 20, 30, 40, 100, 200, 300, 400, 1000, 2000, 3000, 4000 ohms. These coils are all in series and each block on the top of the box is connected to a junction between successive coils. Inserting a plug therefore short-circuits a coil, see Fig. 3. In the 1, 2, 2, 5 plan the construction is similar, but the coils of any group have resistances in the ratio 1 : 2 : 2 : 5. Any resistance from 1 to 10,000 ohms can be obtained by either of these plans. On account of the large number of plugs to be manipulated, the large number of plug contacts and the necessity of making a mental summation of the values unplugged, these arrangements are being superseded in modern resistance boxes by the decade plan described below.

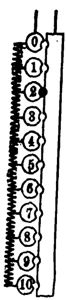

Fig. 4. 10-coil Decade

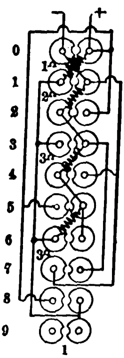

Fig. 5. 4-coil Decade

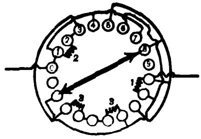

Fig. 6. 4-coil Dial Decade

Decade Plan. — The name decade arises from the use of 10 plug holes (but only one plug) for each group of coils, each hole corresponding to a given number of units, tens, hundreds, etc.

There may be either 10, 9 or 4 coils per set. The 10-coil arrangement is shown in Fig. 4, a 4-coil plug decade arrangement in Fig. 5, and a 4-coil dial decade arrangement in Fig. 6. The 9-coil decade differs from the 10-coil decade only in the omission of the tenth coil.

The only gain in having the tenth coil is to make it possible to check the total resistance of the 10 coils of one decade against any one coil of the next higher decade. The 4-coil arrangement possesses all the advantages of the 9-coil decade, and has the added feature of fewer coils to get out of adjustment.

Precision of Resistance Boxes. — The precision to which the various coils in a resistance box are adjusted depends on the design and use to which the box is to be put. In the cheaper boxes the actual resistance of any coil may differ from the stated resistance by as much as 1/5 per cent, whereas higher grades of boxes can be had having an accuracy of 1/50 per cent.

Precautions to be Taken. Care of Resistance Boxes. — The directions under these same headings given in the article on *Bridges for Electrical Measurements* also apply to the use and care of resistance boxes.

COSTS. — An ordinary 10,000-ohm resistance box (with coils for obtaining all resistances from 1 to 10,000 ohms) with the coils accurate to 1/5 per cent costs about $30. A high-grade 10,000-ohm resistance box with coils accurate to 1/25 per cent costs about $90. The costs of Reichsanstalt standard resistances are approximately as follows:

0.0001 ohm	$40	1 to 1000 ohms	$20
0.001 ohm	30	10,000 ohms	25
0.01 and 0.1 ohm	30		

BIBLIOGRAPHY. — Same as for *Bridges for Electrical Measurements*, q. v.

[H. PENDER AND H. R. RANKEN.]

RHEOSTATS AND RESISTORS. — (*See also Controllers; Control Systems for Railway Motors; Motors; Regulators; Resistors, Standard; Starters, Motor.*) A rheostat is a resistance device, usually adjustable, placed in a circuit for the purpose of regulating the current in that circuit. If used in connection with a machine, it may serve for regulating the speed, input, output, voltage or power factor. The name resistor is also used synonomously with rheostat, but is sometimes limited to mean a non-adjustable resistance device. This article treats primarily of the design of the resistance units, or resistors, used in the various controlling and starting devices employed commercially and in the laboratory; for their application, connections, etc., see the articles listed at the head of this article.

General Principles of Design. — Rheostats used for starting motors or for other intermittent work are usually designed on the assumption that no heat is radiated by them during the period (usually from 15 to 30 seconds) that they are carrying current. On this assumption the maximum allowable current I which a resistor can carry for t seconds without exceeding a temperature rise of T degrees is proportional to the square root of the ratio of T to t, the factor of proportionality depending upon the specific resistance and size of the current conductor, and the specific heats, weights and volumes of the materials heated, including the insulating material in which the resistors are embedded; see *Heat and Thermal Properties*. However, since there are so many variables entering into this factor K, the usual method employed in designing a rheostat is to determine experimentally the relations between current, temperature rise and time for a series of resistance units and to plot these relations in a set of curves. See also below under *Commercial Forms of Rheostats.*

The maximum temperature rise in the case of rheostats designed to carry a continuous load will occur when the heat radiated equals the heat generated. The proper resistance units for any service are determined from capacity curves for a variety of units subject to various conditions. Capacity curves are obtained by plotting as ordinates degrees of final rise of temperature against watts dissipated as abscissas. See also below under *Commercial Forms of Rheostats.* Natural draught is usually depended on for ventilation. For very large capacities forced ventilation is occasionally applied, if the space available is limited, but little is saved on the initial investment, and the maintenance expense is increased.

COMMERCIAL RHEOSTATS. — The term "commercial rheostat" is commonly meant to include besides the resistance elements the complete switching and control mechanism which serves to vary the resistance in the circuit for any particular kind of regulation.

Forms of Resistance Elements for Commercial Rheostats. — The more common forms of resistance elements are described below.

Standard "Unit" Type of Resistance Element. — Units of this type are made in either a flat or cylindrical form. One form of flat unit consists of a moulded flat core of vitreous material on which the resistance wire is wound; the surface is then coated with a special cement and baked. Thus the resistance material is protected from injury and made proof against moisture.

Standard cylindrical units usually have a core of asbestos tubing, or sometimes of metal tube coated with a suitable insulating material, such as enamel. A wire of low temperature coefficient is used; see *Wires, Resistance.* The tube with winding is covered with a suitable insulating compound, and porcelain bushings or metal rings (the latter for the clip type) are placed on the ends. The units are then thoroughly baked and mounted rigidly on a frame or in a suitable case. The coating protects the resistance material from mechanical injury,

forms a good conductor of heat, and in case of a burn-out prevents appreciable arcing and unwinding of the wire. As a further protection, a sheet metal covering is sometimes placed around the cement.

The sizes and capacities of cylindrical units cover the following ranges approximately: power capacity, from 30 to 350 watts; current capacity, from 0.06 to 40 amperes; resistance, from 0.1 to 10,000 ohms; length, from 4 to 22 inches; diameter, from 1 to 2.5 inches. The watt capacity for these resistance units varies from approximately 1.5 to 3.5 watts per square inch of surface for continuous service, when assembled in frames affording good ventilation. This type of rheostat is rarely employed when currents of more than 50 amperes are to be handled.

Plate Type of Resistance Element. — In this type the resistance coils are attached to a circular base of insulating material. The coils are either covered with an insulating, heat-conducting cement and baked, or are enclosed in a ventilated iron case. Suitable contacts and a switch arm are provided. Currents higher than 60 amperes are rarely handled by this type of rheostat. The common sizes of plates range from 9 to 15 inches in diameter.

Grid Type of Resistance Element. — This type of rheostat, Fig. 1, consists of cast-iron grids assembled on horizontal rods bolted to pressed steel end-plates, and is the type generally used for large currents. The rods are covered with a mica insulating sleeve. If mounted on a frame affording good ventilation, the continuous capacity of the standard grids is approximately 700 amperes per square inch of cross section for a maximum rise of 240° C.

Switching and Control Mechanism for Rheostats. — (*See also Starters, Motor.*) With those rheostats which contain distinct resistance elements, or units, the terminals of the elements are brought out to metal contacts usually arranged in a circle on an insulating, fireproof plate. The contact of the switch arm for small currents up to 25 amperes per contact arm consists of an ordinary straight finger contact brush; for currents up to 350 amperes, solid sliding plungers with evenly-faced surfaces held by springs against the contact segments are used in the switch-arms. For higher currents the laminated brush has been found more satisfactory because of the more uniform contact obtained. Most designs are based on the rule that for maximum current, 20° C. rise of temperature above surrounding air should not be exceeded for contacts and face parts. When hand-operated rheostats cannot be mounted on the panel, chain and sprocket drive is usually employed. Gear control is also occasionally used. Large rheostats are frequently operated by solenoids or motors. Motor-operated rheostats are usually employed for currents in excess of 350 amperes.

Special Forms of Commercial Rheostats. — For any particular class of service, the nature of the regulation desired, and the kind of circuit to which the rheostat is to be connected will determine the arrangement, size and number of the resistance steps necessary as well as the proper type of switching mechanism and control. See also *Motors, Industrial Application of.*

Field Rheostats. — The number of steps for a field rheostat depends on the closeness with which adjustments of field current are to be made and on the range desired. For ordinary conditions a rheostat resistance equal to the resistance of the generator field is satisfactory. Machines which are regulated by automatic voltage regulators frequently require a rheostat resistance of from 2 to 4 times that of the generator field. Field rheostats for currents up to 60 amperes are usually in form of the plate type or unit type. For higher capacities the grid type is employed. Field rheostats commonly have from 30 to 70 divisions of resistance. Double this number may be obtained in case of two or more plates, if the plates have the levers staggered. Field rheostats are either hand-controlled or solenoid- or motor-operated.

Field Discharge Resistors. — These resistances are placed across the field of motor or generator whenever the main-line switch is opened, for the purpose of providing a gradual dissipation of the electromagnetic energy stored in the field, thus limiting the arc on opening and reducing the back electromotive force due to the inductance of the field circuit. They are commonly designed for 15-second duty. In general, a resistance equivalent to that of the field is recommended. They are frequently included with the field rheostats.

Starting Rheostats. — See *Starters, Motor.*

LABORATORY RHEOSTATS AND RESISTORS. — (*See also Resistors, Standard.*) On account of the extreme variety of the requirements for rheostats in a laboratory, there are but few standard forms of rheostats for laboratory use on the market. Therefore, most laboratory rheostats are of special design.

A good form of laboratory rheostat for moderately-large currents is one consisting of a thin metal tube, on which enameled resistance wire is wound. The sliders should carry two or more laminated brushes, below which the enamel is scraped off. For fixed resistors the slider is omitted. The continuous capacity of this form of resistor of diameter from 1 inch to 2 inches ranges from 4 to 6 watts per square inch of surface, if ventilation is good.

Grooved porcelain tubes or rectangular slate slabs wound with bare resistance wire will carry on an average from 2 to 4 watts per square inch continuously.

Resistance wire (*see Wires, Resistance*) wound on open wooden frames is frequently used for laboratory rheostats.

Data on Galvanized Iron Wire. — Iron wire, although it has a much lower resistance than the various forms of resistance wires on the market, is much cheaper and is therefore sometimes used. The following data will be found useful in designing iron wire rheostats.

DATA ON GALVANIZED IRON WIRE

B. & S. gage	Circular mils	Maximum* allowable current	Feet required for 110 volts
20	1,022	2.5	594

* In air with free radiation.

Carbon Rheostats. — This type of rheostat consists of a series of carbon plates stacked in a suitable frame and provided with an adjusting screw such that the pressure between the plates may be varied. Alternate plates of two different sizes are sometimes used in large rheostats to secure greater radiating

surface. These rheostats are very useful when continuous variation of resistance over relatively small ranges is desired; they are also very durable and cheap.

Data for the Design of Carbon Rheostats. — The following data is taken from an article by C. R. Moore in the *Elec. Rev. and West. Elec.*, 1912, Vol. 60, p. 672. Carbon plates, either circular or square, varying in thickness from 1/8 to 1/4 inch are satisfactory, the sizes from 1/8 to 3/16 inch being preferable because of the more uniform contact obtained between the plates. Since practically all of the resistance is in the contacts between successive plates the plate surfaces must be *ground very smooth*. The current-carrying capacity for such rheostats varies from 5 to 12 amperes per square inch with an average of 7 amperes per square inch. For temperature rises ranging from 40 to 85° C. the radiating coefficient is from 0.002 to 0.005 watt per square inch of radiating surface per degree centigrade rise. For pressures ranging from 7.5 to 180 lb. per sq. in., the variation in resistance per square inch per contact based on average results is shown in the following table:

RESISTANCE OF CARBON-PLATE RHEOSTATS

Pressure, lb. per sq. inch	Resistance, ohms per sq. in. per contact	Pressure, lb. per sq. inch	Resistance, ohms per sq. in. per contact	Pressure, lb. per sq. inch	Resistance, ohms per sq. in. per contact
7.5	0.0230	35	0.0063	90	0.0029
10.0	0.0185	40	0.0057	100	0.0027
12.5	0.0145	45	0.0052	120	0.0024
15.0	0.0125	50	0.0047	140	0.0021
20.0	0.0100	60	0.0041	160	0.0018
25.0	0.0082	70	0.0036	180	0.0015
30.0	0.0071	80	0.0032		

Example for Design of Carbon Rheostats. — Given a circuit of 5 ohms resistance connected to constant potential mains of 110 volts, the current is to be adjusted between the limit of 17 and 21.5 amperes by means of a series rheostat. Hence the corresponding voltage drops through the rheostat are 25 and 2.5 volts respectively, which calls for a resistance ranging from 1.47 ohms to 0.116 ohm. For a current-carrying capacity of 7 amperes per square inch, the plates must have an area of 21.5 ÷ 7 = 3 sq. in. approximately; square plates 1.75 by 1.75 in. may therefore be used. A convenient thickness for plates of this size is 1/8 in. With 8 lb. per sq. in. as the minimum pressure, the resistance per plate is 0.022 ÷ 3 = 0.0073 ohm (from table and area of plates as computed above). Hence the number of plates for 1.47 ohms resistance is 1.47 ÷ 0.0073 = 200; thus the length of the rheostat is approximately 200 × 0.125 ≒ 25 in. The minimum resistance of 0.116 ohm requires 0.116 ÷ 200 = 0.00058 ohm per plate, which is equivalent to 3 × 0.00058 = 0.00174 ohm per square inch per contact. Hence, from the table the maximum pressure must be 165 lb. per sq. in., which is equivalent to a total pressure of 3 × 165 = 495 lb. acting on the frame supporting the carbon blocks.

Radiating surface must be provided for a maximum of 25 × 17 = 425 watts. With a radiating constant of 0.004 watts per square inch per degree centigrade rise of temperature, a maximum rise of temperature of 75° C. will require a radiation of 0.004 × 75 = 0.30 watts per square inch. Hence a radiating surface of 425 ÷ 0.30 = 1420 sq. in. must be provided. Since the 200 plates represent a radiating surface (edges only) of only 200 × 4 × 0.125 × 1.75 = 175 sq.

in., every other plate must be of a larger size. This may be secured by using 100 small plates 1¾ by 1¾ by ⅛ inch, having a total radiating surface (edges only) of 87.5 sq. in., and 100 plates 3 by 3 by ⅛ inch, having a total edge surface of $3 \times 0.125 \times 4 \times 100 = 150$ sq. in.; the total area of their projecting sides represents $(3 \times 3 - 3) \times 2 \times 100 = 1200$ sq. in. Thus the total radiating surface is $87.5 + 150 + 1200 = 1437.5$ sq. in.

SUBMERGED WIRE RHEOSTATS. — Steady loads for temporary work may be obtained from galvanized iron resistors placed in a river or tailrace or in a barrel continuously fed with supply water. The proper diameter and length of wire for any set of requirements may be calculated from the following formulas:

$$d = KI^{2/3}, \qquad l = \frac{d^2E}{112\,I},$$

in which d = diameter of wire in mils, I = the current in amperes, E = the impressed voltage, l = length of wire in feet, 112 = average value of ohms per mil-foot of galvanized iron wire. Values of K for barrels or tanks range from 3.25 to 2.75, for tailraces or rivers of moderate flow, 2.75 to 2.25, for conditions of rapid flow, 2.25 to 2.0. Wooden sticks with fairly-sharp edges will make reliable supports for the wire. For more careful work the wires may be held by porcelain cleats screwed to wooden frames. The heating of these wires in water is so great that there must be no obstructions to a free circulation of the cooling water, otherwise failure may occur due to the formation of gaseous envelopes surrounding the wire. The water used must be clean to prevent rapid destruction by electrolysis. When tanks or barrels are used, it is preferable to raise the container above the ground (on wooden blocks about two feet high) so as to avoid seriously grounding the circuit through the stream of cooling water.

DATA FOR SUBMERGED RHEOSTATS OF GALVANIZED IRON WIRE

From *Rheostats for Dynamo Load Tests*, Am. Elec., 1903, Vol. 15, p. 512.

WATER RHEOSTATS. — A water rheostat serves as a simple, cheap and satisfactory means of dissipating large amounts of energy. It is extensively used in the commercial testing of apparatus and for other purposes where an adjustable, high-power-capacity resistance is required. Permanent installations are sometimes made in hydroelectric stations to improve hydraulic or electric regulation and to furnish an artificial load.

Resistivity of Water and Common Solutions.—The resistivity of ordinary water at 20° C. (= 68° F.), taken from streams, wells or reservoirs, usually ranges from about 800 to 2000 ohms per inch cube (2000 to 5000 ohms per centimeter cube) though extremes may be found as low as 500 and as high as 5000 ohms per inch cube (1200 and 12,000 ohms per centimeter cube respectively). In water rheostats designed for less than 1000 volts it is usually desirable to increase the conductivity of the water by adding a salt (common salt, copper sulphate or other cheap salt) or an acid (usually sulphuric). For example, the resistivity of a 5 per cent solution of common salt at 18° C. is 14.9 ohms per inch cube (38 ohms per centimeter cube). The resistivity of various solutions of different strengths is given in the article on *Resistance and Conductance.*

As noted in the article just referred to, the resistance of ordinary water and of salt and acid solutions diminishes rapidly with increase of temperature. To a close approximation the change in the resistance of ordinary clean water between 0° C. and 100° C. may be calculated from the formulas

$$R_t = \frac{40\,R_{20}}{20 + t}, \qquad \text{or} \qquad R_{t'} = \frac{72\,R_{68}}{4 + t'}.$$

where R_{20} is the resistance at 20° C. = R_{68}, the resistance at 68° F., and t is any other temperature centigrade and t' any other temperature Fahrenheit.

Before designing a large high-voltage rheostat it is desirable to determine both the resistivity and temperature coefficient of a sample of the water which will be used. The sample should be tested in a miniature, low-voltage rheostat. If the large rheostat is to be operated on alternating current, the test with the miniature rheostat should also be made with alternating current, in order to avoid the effects of polarization. Determinations for a direct-current rheostat should be made with direct current, using a miniature rheostat of the same materials as are to be used in the large rheostat, and operated at the same current density and voltage. In designing a rheostat for permanent use data should also be obtained on the variations in the resistivity of the water throughout the year, for these variations are very marked in some cases.

Low-voltage Water Rheostats. — A simple form of water rheostat for direct-current or single-phase low-voltage work can be made of an oil barrel and two iron plates. One plate is placed on the bottom of the barrel. An insulated copper wire is connected to this plate and brought up along the side of the barrel and out through the top, or it may be attached to the underside of the barrel by means of a bolt passing through the plate and the bottom of the barrel. The other terminal is attached to a movable plate which is held by a window cord strung over two pulleys, the plate being held in position by a suitable counterweight at the free end of the cord. The barrel is filled with water, to which a relatively strong solution of common salt ($NaCl$), sal ammoniac (NH_4Cl) or washing soda (Na_2CO_3) is added in sufficient amount to give the required conductivity. It is essential that the substance should be dissolved before it is added to the water barrel and that the solution should be poured in very carefully, because a very small amount of a salt solution will add considerably to the conductivity of the water. A single-phase load of 100 amperes at 100 volts may be carried continuously in a 40-gallon barrel without causing the water to boil. The plates should have a surface (one side only) of at least 1 square inch per ampere.

For low-voltage three-phase work a barrel with three pipes, suitably mounted and arranged to be raised or lowered by means of a cord and pulleys, is sometimes used. The pipes should have an immersed surface (outside surface only) of at least 1 square inch per ampere.

A serious objection to the use of a water rheostat containing a salt or acid is that the resistance for a given setting of the electrodes does not remain constant, due to the evaporation of the water, rendering the solution more concentrated. The increase in the temperature of the solution also causes very appreciable changes in resistance. When direct current is used the change in the concentration of the solution at the two electrodes (polarization) also causes a variation in the resistance with time.

High-voltage Water Rheostats. — For voltages above 1000 the conductivity of the tap or river water available is usually ample, without having recourse to the use of salts or acids. The use of ordinary water also makes it possible to keep a continuous flow of water through the rheostat and thus maintain a practically constant temperature. The discussion of such high-voltage rheostats given below is adapted from an excellent paper on this subject by E. A. Ekern in the *Stone and Webster Public Service Journal* for Nov., 1911.

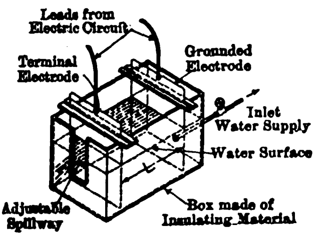

Fig. 1. Open-column Type

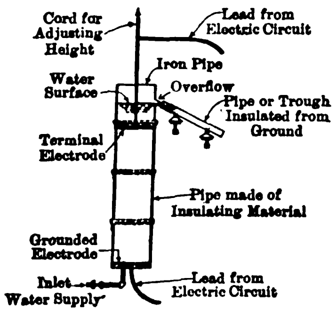

Fig. 2. Closed-column Type

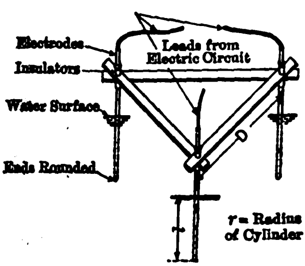

Fig. 3. Open Type, Three-phase Rheostat

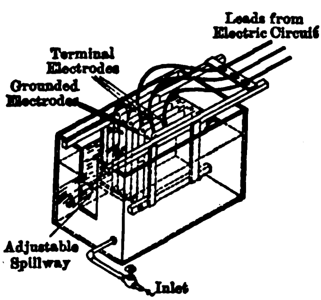

Fig. 4. Mixed Type, Three-phase

Types of High-voltage Water Rheostats. — Fig. 1 illustrates a simple form of such a rheostat, and will be referred to as the "open-column" type, and Fig. 2 illustrates another simple form which will be referred to as the "closed-column" type. The illustrations are for single-phase rheostats; three-phase rheostats are made by combining three single-phase elements with the neutral point grounded. Fig. 3 illustrates a three-phase type suitable for immersion

in an open body of water; this type will be referred to as the "open type." The type shown in Fig. 4, which is a combination of the column type and open type, will be referred to as the "mixed type;" the illustration shows a three-phase rheostat with three plates for terminal electrodes sandwiched between four neutral electrodes. The plates should preferably have rounded edges.

Calculation of Resistance. — The resistance of the column type of rheostat (Figs. 1 and 2) is computed by the formula

$$R = \rho \frac{L}{A}, \tag{1}$$

where ρ = the resistivity of the water in ohms per inch cube (as noted above ρ is usually between 800 and 2000 ohms per inch cube), L = the length of the column in inches, and A = the area of the cross section of the column in sq. in.

For the open type (Fig. 3) the resistance between any cylindrical electrode and the neutral is given by the formula

$$R = \frac{\rho}{2.73\, l} \log_{10}\left(\frac{2\, D}{d}\right), \tag{2}$$

where ρ = the resistivity of the water in ohms per inch cube, l = the wetted length of cylinder in inches, D = distance between cylinders in inches (center to center), and d = external diameter of each cylinder in inches. The equation is sufficiently accurate for all practical purposes when $2\, D \div d$ is greater than 80 and may be used with but small error when this ratio is as low as 40. (*See also the article on Resistance and Conductance.*)

The resistance to neutral of the mixed type (Fig. 4) is computed by the formula

$$R = \frac{R_1 R_2}{R_1 + R_2}, \tag{3}$$

where

$$R_1 = \rho \frac{S}{2\, A} \qquad \text{and} \qquad R_2 = \frac{\rho}{1.37\, \lambda} \log_{10}\left(\frac{4\, S}{t}\right), \tag{4}$$

R_1 is the resistance between the face of any one terminal plate and the two neutral plates between which it is placed and R_2 is the resistance between the wetted edge (assumed rounded) of the terminal plate and the two plates between which it is placed. The letters in the expressions for R_1 and R_2 have the following meanings: ρ = resistivity of the water in ohms per inch cube, S = the distance between adjacent plates (terminal plate to neutral plate) in inches. A = area in square inches (one side only) of terminal plate, t = thickness of each terminal plate in inches, λ = total length in inches of wetted edge (perimeter) of one terminal plate. The expression for R_2 is a rough approximation, but as R_2 is small compared with R_1, the error in the resultant resistance R due to an error in R_2 is relatively small.

Allowable Current Density. — A current density at the electrodes in excess of 4 amperes per square inch is accompanied by a "spitting" or arcing and there is danger of short circuit. This limiting current density applies to clean water, but as there is always a likelihood of foreign materials getting into the water, it is not advisable to use a current density between flat plates in excess of 1 ampere per square inch, but at the edges of the plates or where there is a free and large circulation of water a current density as high as 3 amperes per square inch may be safely used.

Minimum Distance between Electrodes. — Calling σ the maximum allowable current density and v the voltage to neutral, then in terms of the notation defined above, the minimum spacing of the electrode is;

For column type (Figs. 1 and 2) $$L = \frac{v}{\rho \sigma}. \tag{5}$$

For open type (Fig. 3) $$D = \frac{d}{2} \log^{-1}\left(\frac{0.869\, v}{\rho d \sigma}\right). \tag{6}$$

In the mixed type the limiting current density is usually at the edge of the plates, and the minimum spacing in this case is given by the relation:

For mixed type (Fig. 4) $$S = \frac{t}{4} \log^{-1}\left(\frac{0.869\, v}{\rho t \sigma}\right). \tag{7}$$

The logarithms are all common logarithms (i.e., to the base 10).

Minimum Size of Electrodes. — Using the same symbols as above, and in addition calling I the current per phase (terminal to neutral), the minimum area of each plate in the column type (Figs. 1 and 2) is $A = I \div \sigma$ square inches, and in the open type (Fig. 3) the minimum diameter of the electrodes is $d = I \div (\pi l \sigma)$ inches. In the mixed type the total area of the terminal plate (both sides and the edges) is approximately $(\rho S) \div R$, where R is the total required resistance. The area of the flat surface of the plate (one side only) may be taken from 10 to 15 per cent less than half of this total surface, to allow for the edges. The actual division of current between the edges and the flat surfaces will be inversely as the resistances R_1 and R_2 given by equations (4).

Example of Calculation of Dimensions. — The more complicated case of a mixed type of rheostat is chosen, to illustrate the use of both types of formulas. Power to be dissipated 3000 kw. at 2300 volts, three-phase. Then voltage to neutral is $V = 1328$ volts, current per phase $I = 753$ amperes, corresponding to a resistance of 1.762 ohms. Assume the plates to be ¼ inch thick, then $t = 0.25$. Allowing a maximum current density of 3 amperes per sq. in. at the edges, and taking $\rho = 800$, the minimum spacing is then, from equation (7), $S = 5.27$ inches.
The total surface (both sides and edges) of each terminal plate, assuming $\rho = 1200$, to allow for an increase in the assumed resistivity of the water, will be $(1200 \times 5.27) \div 1.762 = 3580$ sq. in., and the area of the plate should then be say 15 per cent less than $3580 \div 2$, or 1500 sq. in. approximately. A plate 60 by 25 inches will be a suitable size. The two resistances R_1 and R_2 are then from equation (4), $R_1 = 2.1$ ohms and $R_2 = 11.6$ ohms, and from equation (3) $R = 1.775$, which practically agrees with the required value of 1.762 ohms.

Supply of Water. — Due to the change in the resistivity of water with increase in temperature it is preferable to supply the rheostat with sufficient water to prevent much of an increase of temperature. At a hydroelectric station it is usually possible to use an open-type rheostat (Fig. 3) placed in a running stream or in a large body of water. When the water supply is limited it is sometimes necessary to allow the water to heat or even boil in extreme cases. Even in the case of limited water supply, however, a small steady overflow should be allowed, in order to prevent an accumulation in the rheostat of the salts contained in the water.

For an increase of $T°$ F. in temperature the water required to carry off P kilowatts, assuming no radiation or evaporation, is

$$\frac{0.91\, P}{T} \text{ cu. ft. per min.} = \frac{6.8\, P}{T} \text{ gallons per min.} \tag{8}$$

If only G gallons of water per minute are available and the water is allowed to boil, then calling T the difference between the boiling point and the temperature of the supply water in degrees Fahrenheit, the water evaporated when P kilowatts are supplied to the rheostat would be

$$G_e = \frac{P}{143} - \frac{GT}{970} \text{ gallons per min.} \tag{9}$$

Example. — To dissipate 3000 kw. with a 10° F. rise in the temperature of the water would require (6.8 × 3000) ÷ 10 = 2040 gallons per min. If only 60 gallons per minute are available at 62° F., $G_e = 3000 \div 143 - 60 \times (212 - 62) \div 970 = 11.7$ gallons per min. will be evaporated, leaving 48.3 gallons per minute for the overflow.

Notes on Design of Water Rheostats. — The column type of rheostat may be used for any capacity and voltage. For voltages up to 23,000, the mixed type is usually preferable for large loads. For higher voltages, the open type may then be employed to advantage. Common iron pipe or steel plates are satisfactory materials for electrodes. Rheostats designed for permanent use should have galvanized electrodes. For voltages of 2300 volts and less, well-oiled and shellacked wooden containing vessels for the water have been found satisfactory. Open-or mixed-types of rheostats may be put in any tank or body of water where the clearance to sides or bottom is greater than one-half the spacing of electrodes. Column type rheostats up to 44,000 volts having columns built of vitrified glazed tile cemented together with Portland cement shellacked over have been operated successfully. Open-type rheostats made of iron pipes insulated and held securely above the water surface are very satisfactory. Mixed-type rheostats having plates separated by common porcelain line insulators and all clamped into a wooden frame have been used very successfully. Plates or electrodes should always be so arranged and located as to obtain free circulation of water. Where insulating material may be partially or intermittently in and out of the water, material may be deposited from the water and sufficient leakage surface must be provided. Innumerable arrangements and contrivances for the operation of rheostats may be designed but the important considerations are sufficient insulation to protect the operator, and positive movements to obtain the required degree of adjustment. Water rheostats are practically non-inductive. A slightly-leading current is obtained due to electrostatic capacity, but it is often more than offset by the inductive reactance of the conductors.

ROOTS AND POWERS. — The symbol a^n where n is a positive whole number means a multiplied by itself n times; n is called the exponent of a. The conception of an exponent is also extended to include negative and fractional exponents as follows: Let m be a positive whole number and let $n = -m$; then the expression $a^n = a^{-m}$ is defined as equivalent to $\frac{1}{a^m}$; that is, a^{-m} is taken as equivalent to the reciprocal of a^m. Again, let m be a whole number and let $n = \frac{1}{m}$; then the expression a^n is defined as equivalent to $a^{\frac{1}{m}} = \sqrt[m]{a}$; that is, $a^{\frac{1}{m}}$ is taken to represent the m root of a. In general, then, the properties of exponents are the following, where m and n may be positive or negative whole numbers or fractions:

$$a^{-m} = \frac{1}{a^m} \qquad (a^m)^n = a^{mn}$$

$$a^{\frac{1}{m}} = \sqrt[m]{a} \qquad \sqrt[n]{a^m} = a^{\frac{m}{n}}$$

$$a^m a^n = a^{m+n} \qquad a^0 = 1$$

$$\frac{a^m}{a^n} = a^{m-n}$$

The calculation of roots and powers can be conveniently carried out by means of logarithms (q. v.); for the highest accuracy, a seven or nine place table should be used. Note that

$$\log a^n = n \log a$$

$$\log \sqrt[n]{a} = \frac{1}{n} \log a$$

[W. A. Del Mar.]

ROPES AND ROPE DRIVE. — (*See also Wires and Cables, Bare.*) The following terms relating to ropes and cordage are commonly employed:

Yarn. — Natural fibers twisted together.
Thread. — Two or more *small yarns* twisted together.
String. — Same as thread except of little larger yarns.
Strand. — Two or more *large yarns* twisted together.
Cord. — Several *threads* twisted together.
Rope. — Several *strands* twisted together.
Hawser. — A rope of three *strands*.
Shroud-laid rope. — A rope of four strands.
Cable. — Three *hawsers* twisted together.

In a strand the yarns are laid up left-handed; in a rope the strands are laid up right-handed; in a cable the hawsers are laid up left-handed.

WEIGHT AND STRENGTH OF ROPES. — The following tables give the weight per foot and breaking strength of hemp and steel ropes. Cotton ropes have approximately the same weight per foot as hemp ropes, but their breaking strength is only 60 per cent of that of hemp ropes. Iron ropes have the same weight per foot as steel ropes, but only 50 per cent of the breaking strength of cast-steel ropes.

APPROXIMATE BREAKING STRENGTH OF STEEL-WIRE ROPES

(*Trenton Iron Company*)

6 strands of 19 wires each					6 strands of 7 wires each

1¼	0.53	10,900	2½	2.13	43,700

Factor of Safety. — For ordinary purposes the maximum safe stress in wire ropes should be about one-third the ultimate, and for shafts and elevators about one-fourth the ultimate. In estimating the stress due to the load for shafts and elevators, allowance should be made for the additional stress due to acceleration in starting. For short inclined planes not used for passengers a factor of safety as low as 2½ is sometimes used, and for derricks in which large sheaves cannot be used and long life of the rope is not expected, the factor of safety may be as low as 2.

For power transmission by hemp ropes a factor of safety of 36 (referred to the nominal strength of the rope) is usually employed (*C. W. Hunt, Trans. A.S.M.E., Vol. 12, p. 230*).

Splicing and Knots. — See *Kent's Mechanical Engineers' Pocket-Book.*

ROPE DRIVING. — There are two methods of putting ropes on the pulleys, the multiple-rope and the single-rope systems. In the multiple-rope system several endless ropes are employed, and therefore there are as many splices as there are single ropes. In the single-rope system one endless rope is used, making several turns around the pulleys or sheaves, and therefore with but a single splice. In the first case the individual ropes are spliced in place, being made very taut at first, and less so as the rope lengthens, stretching until it slips, when it is respliced. In the second method tension pulley must be used to give the necessary adhesion and also to take up the wear.

Power Transmitted by a Rope. — The formulas given in the article on *Belts and Belting* are directly applicable to rope transmission, but may be put in a more convenient form as follows. Let

V = velocity of rope, in feet per minute,
d = diameter of rope, in inches,
m = weight, in pounds, of 1 foot of rope 1 inch in diameter,
T_1 = actual tension in driving side of rope, in pounds per circular inch (i.e., the tension in pounds in a rope 1 inch in diameter),
f = coefficient of friction between rope and pulley,
n = number of half-turns the rope makes around pulley,
$C = 1 - \epsilon^{-nf\pi}$, where the value of $\epsilon^{-nf\pi}$ is taken from the table of ϵ^{-x} in the article on *Exponential Functions*, putting $x = nf\pi$.

Then horse-power transmitted by each taut rope from one pulley to the other is

$$P = \frac{CT_1d^2V}{33,000}\left(1 - \frac{mV^2}{116,000\,T_1}\right). \tag{1}$$

Power Transmitted by Hemp Rope. — A formula developed by C. W. Hunt (*Trans. A.S.M.E., Vol. 12, p. 230*) is frequently employed. This formula may be written

$$P = \frac{d^2V}{248}\left[1 - \left(\frac{V}{8500}\right)^2\right], \qquad (2)$$

which is the same as formula (1) when $n = 1$, $f = 0.35$, $C = 0.67$, $m = 0.32$ and $T_1 = 200$. The following table is calculated from Hunt's formula. For temporary work a rope of given diameter may be used with safety to transmit twice the horse power given in the table.

HORSE POWER TRANSMITTED BY HEMP ROPE AT VARIOUS SPEEDS

Computed from formula (2) given above

Diam. of ropes, inches	Speed of the rope in feet per minute									
	1500	2000	2500	3000	3500	4000	4500	5000	6000	7000
½	1.45	1.9	2.3	2.7	3.0	3.2	3.4	3.4	3.1	2.2
⅝	2.3	3.2	3.6	4.2	4.6	5.0	5.3	5.3	4.9	3.4
¾	3.3	4.3	5.2	5.8	6.7	7.2	7.7	7.7	7.1	4.9
⅞	4.5	5.9	7.0	8.2	9.1	9.8	10.8	10.8	9.3	6.9
1	5.8	7.7	9.2	10.7	11.9	12.8	13.6	13.7	12.5	8.8
1¼	9.2	12.1	14.3	16.8	18.6	20.0	21.2	21.4	19.5	13.8

1¾	18.0	23.7	28.2	32.8	36.4	39.2	41.5	41.8	37.4	27.6
2	23.2	30.8	36.8	42.8	47.6	51.2	54.4	54.8	50.0	35.2

Power Transmitted by Iron and Steel Ropes. — Wm. Hewitt of the Trenton Iron Company gives the following formula for the power transmitted by a steel rope, excluding the losses due to journal friction of the sheaves,

$$P = Bd^2v, \qquad (3)$$

where v is the velocity of the rope in *feet per second* and B has the following values.

B for steel rope on	Number of half turns around sheave = n					
	1	2	3	4	5	6
Iron	5.61	8.81	10.62	11.65	12.16	12.56
Wood	6.70	9.93	11.51	12.26	12.66	12.83
Rubber or leather	9.29	11.95	12.70	12.91	12.97	13.00

For iron rope take for B one-half the figures given in the above table.

Hewitt's formula (3) is equivalent to (1) when the centrifugal force of the rope is neglected and T_1 and f are as follows:

Kind of rope	Working tension T_1 in lbs. per circ. inch		Coeff. of friction $= f$
	Iron	Steel	
Iron	3600	7200	0.16
Wood	3600	7200	0.23
Rubber or leather	3600	7200	0.40

It should be noted that the coefficient of friction decreases rapidly with moisture or grease on the rope and sheaves, and consequently to transmit a given amount of power the tension must then be increased.

In the following table is given the horse-power that may be transmitted by a steel rope making a single half turn ($n = 1$) on wood-filled sheaves. This table agrees approximately with formula (3). The transmission of more than 250 h.p. by a single steel rope making a single half turn on filled sheaves is impracticable, as the filling would be rapidly cut out due to the increased tension (i.e., total tension $= T_1d^2$) and high velocities required. If the rope makes several half turns around the sheave, however, a greater amount of power can be transmitted at a given speed and tension than when only a single half turn is used.

HORSE-POWER TRANSMITTED BY A STEEL ROPE ON WOOD-FILLED SHEAVES

Diameter of rope, in.	Velocity of rope in feet per second									
	10	20	30	40	50	60	70	80	90	100
1/4	4	8	13	17	21	25	28	32	37	40
5/16	7	13	20	26	33	40	44	51	57	62
3/8	10	19	28	38	47	56	64	73	80	89
7/16	13	26	38	51	63	75	88	99	109	121
1/2	17	34	51	67	83	99	115	130	144	159
9/16	22	43	65	86	106	128	147	167	184	203
5/8	27	53	79	104	130	155	179	203	225	247
11/16	32	63	95	126	157	186	217	245	...	...
3/4	38	76	103	150	186	223	...	...	...	...
7/8	52	104	156	206	...	...	...	...	...	...
1	68	135	202	...	...	...	...	...	...	...

The horse-power that may be transmitted by iron ropes is one-half of the above.

Power Lost Due to Friction of Sheaves and Shafts. — In the above formula no allowance is made for the friction of the sheaves and shafts. Wm. Hewitt of the Trenton Iron Company gives the following expression for the horse-power lost in friction

$$6 \times 10^{-6} (W + G_1 + G_2) v,$$

where $W =$ total weight of rope, $G_1 =$ total weight of terminal sheaths and shafts, $G_2 =$ total weight of intermediate sheaves and shafts, all in pounds, and $v =$ velocity of rope in feet per second.

Diameters of Sheaves. — The following table gives the minimum diameter of sheaves recommended by Hunt for hemp ropes and by Hewitt for steel and iron ropes. The larger the diameter of the sheaves the greater the life of the rope.

MINIMUM DIAMETER OF SHEAVES

Diameter of rope, in.	Hemp	Steel			Iron		
		7-wire	12-wire	19-wire	7-wire	12-wire	19-wire

1¾	72	..	..	..	...	...	..
2	84	..	..	..	...	...	..

Tension Measured by Sag. — (*See also article on Transmission Lines.*) Let

w = weight of rope per foot, in pounds,
L = distance between centers of sheaves in feet,
S = sag in feet midway between sheaves.

Then the tension at the sheaves, corresponding to the sag S, is approximately

$$T = \frac{wL^2}{8S} + wS \qquad \text{pounds}$$

for either the driving or the slack rope.

[Wm. Kent.]

RUBBER. — (*See also Gutta-Percha; Insulating Materials; Wires and Cables, Insulated.*) Rubber is derived from the milky secretion or latex of certain tropical trees, creepers and shrubs found chiefly in America, Africa, Ceylon and Malacca. When these plants are tapped, a thick milky-looking fluid or latex exudes from them. This latex is composed of very minute oil-like refractive globules, varying in size, which are in a state of rapid Brownian movement in a clear transparent liquid, called the serum. Besides these *caoutchouc* globules, or rubber-gum proper, the serum contains resins, protein, enzymes and various organic and inorganic compounds. Rubber or India rubber is the dried-up or coagulated latex. In Brazil coagulation is effected principally by dry heat or smoking. A wooden paddle is dipped in the latex and held over a smoky fire until the latex has coagulated. This process is repeated until the caoutchouc layers have become sufficiently thick, when the lump of raw rubber is cut off, dried for several days and despatched usually as "fine Para biscuits" to a trading center. It is believed that the excellence of Para rubber is partly due to this mode of preparation, the smoke having a preservative effect and the coagulation in concentric layers adding greatly to the "nerve" of the rubber. Para entrefine, Negro Heads and Sernamby are usually prepared from fine Para rubber which adheres to the tree during tapping or to the vessels containing the latex.

IMPURITIES IN COMMERCIAL RUBBER. — Commercial rubber contains, in addition to the caoutchouc, a number of foreign substances, such as sand, bark, etc., which can be removed by mechanical washing, followed by drying.

Acetone Extract. — In addition to the pure rubber gum, washed rubber contains resins and proteins which are soluble in acetone and are therefore often known as "acetone extract."

The accompanying table shows the loss in washing and the percentage of acetone extract in the best brands of raw rubber.

IMPURITIES IN COMMERCIAL RUBBER

(*Abstracted from a very comprehensive table in "Lectures on India Rubber," Edited by D. Spence, London, 1909.*)

Brazilian Rubber

Trade name	Geographical origin	Mean loss on washing, per cent	Acetone extract in washed dry rubber, per cent
Para, fine Island, soft cure	Brazil, the islands of the lower Amazon and its delta, and also other parts of the State of Para	17–20	1.9–2.1
Para entrefine, Islands entrefine		18–25	Varies
Negro Heads, or Islands Coarse Sernamby		35–40	2–6
Fine Para, upriver, hard cure	Amazon district. Also the districts drained by its large tributaries	15–20	1.9–2.9
Upriver entrefine, hard entrefine		18–25	Varies
Upriver coarse or Manaos Scrappy Negroheads		18–25	1.5–1.8
Cameta Negroheads	Southwestern Para	37–42	1.2–2.2

MANUFACTURE OF RUBBER INSULATION. — The washed, dried rubber is passed between heavy rollers and flattened into thin sheets. It is then cut into small pieces and again passed through the rollers with a large proportion of fine powder consisting usually of inert mineral substances, wax, hydrocarbons and sulphur. The mixture is thus masticated until all its constituents are thoroughly mixed and a smooth homogeneous paste obtained. This process is known as compounding.

Adulterants Used in Compounding. — Experience has shown that 60 or 70 per cent of mineral adulterant, or even a greater proportion of rubber substitute, may be added to rubber gum, before the essential qualities of the rubber

cease to predominate. The majority of commercial 30 per cent insulating compounds have compositions which fall within the following limits.

Ingredient	Per cent
Rubber	30–32
Whiting	0–30
Zinc oxide	28–67
Litharge	1–12
Ozokerite or paraffin	2–4

In addition to the above adulterants, from 2% to 4% of sulphur is added to the compound, the greater part of which combines with the rubber in the vulcanizing process (see below).

Barium sulphate, sublimed white lead, lead carbonate, lamp-black, talc, magnesium carbonate, red lead, barium carbonate and other substances are also used in small quantities. Talc is often objected to, as making the compound porous, and lampblack, as rendering analysis difficult.

Applying the Compound to Wires. — The rubber compound is applied to the wire by "tubing" machines, or is applied in strips, and the wire thus covered with the compound is coiled up ready for vulcanizing. See article on *Wires and Cables, Insulated.*

Vulcanizing. — If exposed for a long time to air and sunlight, rubber looses its elasticity and finally oxidizes completely into resinous matter soluble in acetone. By vulcanization, however, rubber is rendered more or less immune from deterioration by weathering. Vulcanization is the chemical union of rubber gum with sulphur or sulphur chloride. It takes place at a temperature of from 248° to 302° F.

The coils of wire, covered with the compound as above described, are placed in a suitable chamber to which steam at the proper temperature is admitted. The time required for vulcanization depends upon the thickness of the insulation, the nature of the compound, the temperature and pressure of the steam, etc., ranging from 2 to 8 hours.

Sulphur Required for Vulcanization. — The amount of sulphur required to produce vulcanization varies with the brand of rubber and the nature of the adulterants with which it is mixed. The ratio of the weight of combined sulphur to the weight of caoutchouc, which is insoluble in acetone, is called the vulcanization coefficient. The highest grades of 30 per cent Para insulation usually have a coefficient between 5 per cent and 10 per cent.

The vulcanization of some brands of rubber cannot be accomplished without either an excess of sulphur or the presence of some mineral accelerator, such as red lead. Such rubber is to be avoided where permanency is an important consideration. It does not follow from this that red lead is a detrimental ingredient.

SPECIFIC RESISTANCE. — The specific resistance of 30 per cent Para rubber compounds is extremely variable, all values between 150 millions and 4000 millions of megohms per inch cube at 60° F., after electrification for one minute, being encountered. Cable manufacturers usually specify the specific resistance in terms of the constant K in the following logarithmic equation (*see Wires and Cables, Insulated*).

$$M = K \log_{10} \frac{D}{d},$$

where

M = insulation resistance of a cable, megohm-miles,
d = diameter of cylindrical conductor,
D = diameter of cable over its insulation,
K = 5.8 × (millions of megohms per inch cube at 60° F.).

Hence K varies from 870 to 23,000, but its usual commercial value is between 3000 and 8000.

The specific resistance is some indication of the proportion of rubber gum, in the sense that other conditions being equal, it increases with the amount of gum. It also depends upon the dryness, it being often possible to double the megohms by drying the compound in a dessicator. It is even more affected by the amount of mineral wax present, this substance closing the pores and itself possessing a very high resistance. Furthermore, strip-laid compound has greater specific resistance than the seamless.

Temperature Coefficient of Resistance. — The specific resistance of rubber compound decreases rapidly with increase of temperature, this variation being somewhat less, the greater the proportion of rubber gum in the compound. At any temperature T the rate of change of the resistance per degree of temperature rise is approximately proportional to the resistance R at this temperature, i.e.,

$$\frac{dR}{dT} = -CR,$$

where C is a constant, which for high-grade 30 per cent Para compound ranges from 0.02 to 0.03, the usual value being 0.025. The minus sign before the C indicates that the resistance actually decreases with rise of temperature.

Calling R_{60} the resistance at 60° F., and integrating this equation gives for the resistance at any other temperature T the relation

$$R_T = R_{60}\,\epsilon^{(60-T)C}.$$

See article on *Exponential Functions* for values of ϵ^x.

Change of Resistance with Time of Electrification. — The apparent specific resistance of rubber decreases with the time of electrification, a steady state being reached after a period of electrification, depending upon the temperature, this period being less the higher the temperature. Above 120° F. the steady state is reached almost immediately; at ordinary testing temperatures, such as 80° F. to 100° F., the steady state is not reached for an hour or more.

DIELECTRIC STRENGTH. — The disruptive strength of rubber insulation is generally given as between 350 and 450 kilovolts per inch or about 14 to 18 kilovolts per millimeter, effective a–c. values (*E. Jona, Proc. Inst. Elect. Eng., St. Louis, 1907, Vol. 2, p. 550; H. Osborne, Trans. A.I.E.E., 1910, Vol. 29, p. 1553, etc.*). The usual stresses in commercial testing do not exceed one-half of the above amounts. A series of tests with alternating voltage on high-grade commercial wires in 3-foot lengths gave an average dielectric strength of about 600 kilovolts per inch, effective value, with progressively-increasing testing potential.

The disruptive strength, however, is not a constant quantity; it depends upon the time of application of the testing potential, amount of moisture present and upon the temperature.

The relation between dielectric strength and time of electrification is given approximately by the following table:

SPECIFIC INDUCTIVE CAPACITY. — The specific inductive capacity of pure rubber is about 2.3 (*Floy*), but the vulcanized compounds used for insulation have specific capacities ranging between 3 and 4. The specific capacities of several compounds of stated composition are given by E. Jona (*St. Louis, 1904*), but they cannot be considered as representative of American practice.

Time of electrification, minutes	Relative dielectric strength
1	130
3	110
5	100
10	90
15	85
30	80

SPECIFICATIONS. — Specifications for rubber insulation for wires and cables will be found under *Wires and Cables, Insulated*.

[W. A. Del Mar.]

SECHOMETER. — (*See also Bridges for Electrical Measurements.*) The sechometer is an instrument used in connection with a Wheatstone bridge for changing the direct current from a battery to an alternating current, and commutating the portion of this current that flows in the galvanometer circuit to a direct current. The sechometer may be used in the measurement and comparison of self-and mutual inductances and in the measurement of the resistance of electrolytes.

Fig. 1 shows the relative position of the commutators and brushes of a sechometer when connected in a bridge circuit. *A* is the commutator to which the galvanometer is connected and *B* the one to which the battery is connected. They are on the same shaft and turn together.

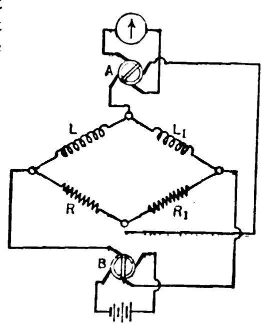

Fig. 1. Connections for Sechometer

The sechometer is not an altogether satisfactory instrument, due to the variation in the various contact resistances when used for any length of time. Whenever possible some other method of accomplishing the desired results should be employed, e.g., the use of alternating current with some sort of a-c. detector, such as a telephone receiver, electrodynamometer or a-c. galvanometer.

[H. Pender and H. R. Ranken.]

SELENIUM. — Selenium, an element of rare occurrence in nature, is found in sulphur and as a selenide in combination with various metals. Vitreous selenium, i.e., selenium which has been fused, is dark brown in color and has a specific gravity of 4.28. Its melting and boiling points are 217° C. and 700° C. respectively. Vitreous selenium is a very poor conductor of electricity, its resistance being about 60,000 ohms per centimeter-cube at room temperature. When vitreous selenium is annealed it assumes a crystalline form sometimes called metallic selenium. As a result of the annealing process, the electrical resistance is considerably reduced (the amount depending upon the thoroughness of the annealing) and becomes a function of the intensity of illumination, a property which is possessed to a lesser degree by tellurium and carbon.

Light-sensitive selenium is said to be light-positive or light-negative depending upon whether its resistance decreases or increases respectively when carried from dark to light. Sensitive selenium is usually light-positive. The resistance of light-negative selenium is usually less than that of light-positive selenium.

SELENIUM LIGHT-CELLS. — A selenium cell or unit is made by connecting several narrow strips of light-sensitive selenium in parallel between the edges of two brass plates. The higher the resistance the higher the sensibility of such a cell, that is, the greater the ratio of its conductivity in the light to its conductivity in the dark. The conductivity of a cell made of high-resistance selenium may show a change in conductivity of 20,000 per cent (200 times) when taken from direct sunlight to a dark room. Cells made of low-resistance selenium (light-negative) show a much smaller change in conductivity, seldom over 50 per cent for a change from direct sunlight to dark.

Effect of Intensity of Illumination. — The resistance of the cell when exposed to light depends upon the time of exposure and the intensity of the illumination. If a strong light is suddenly thrown upon a high-resistance cell placed in a dark room, the resistance of the cell decreases to its minimum value in a fraction of a second and then begins slowly to increase again. If the intensity of illumination is not so great or the cell has a comparatively low resistance the time taken to reach a minimum resistance may be several minutes. The majority of experimenters on this subject agree that the change of resistance varies as the square root of the intensity of illumination.

Effect of Wave Length of Light, Temperature, etc. — It is found that the greenish-yellow rays are the most effective. The sensibility of most cells decreases as the temperature increases. In certain selenium cells a large potential difference impressed across the terminals of the cell produces a variation of resistance in the cell similar to that caused by an exposure to light.

Uses of Selenium Cells. — The light-sensitive property of selenium has been utilized in the photophone and in connection with the electrical transmission of pictures. In the photophone a beam of light reflected from a mirror attached to the vibrating disk of a telephone transmitter is made to play across a selenium cell connected in series with a battery and a telephone receiver. In this manner, speech may be transmitted through space by means of light waves.

In the transmission of pictures a large number of selenium cells are usually made to reproduce the light and shade of the picture. The light reflected from each point on the picture is then represented at the distant point by a corresponding intensity of current, which may reproduce again electrochemically the intensity of the reflected light at each point.

[R. G. Hudson.]

SEPARATORS, STEAM. — (*See also Boilers.*) Ordinary forms of steam boilers, without superheaters, generally deliver steam containing not more than 1.5 per cent of moisture. When the water level rises too high, however, or when the water contains substances which cause foaming, the percentage of moisture in the steam may be much higher. Condensation in long lines of steam pipes also increases the moisture, and for this reason it is customary to place in the pipe line near the engines one or more steam separators. These usually operate by suddenly changing the direction of the flowing steam, so that the particles of water are by their momentum carried out of the flowing current and projected against a baffle or bend in the pipe or separator chamber, where they are collected and removed through a trap. Separators are also frequently installed in the exhaust steam piping to eliminate the cylinder oil contained in the exhaust steam.

[WM. KENT.]

SERIES, MATHEMATICAL. — (*See also Equations, Differential; Wave Analysis.*) In calculating the numerical values of a function for given numerical values of the variable, it is frequently convenient to express the function as a sum of a series of terms each of which is a simple algebraic function of the variable. The simplest form of such a series is the

Binomial Theorem. —

$$(x+a)^n = x^n + nax^{n-1} + \frac{n(n-1)}{2!}a^2x^{n-2} + \frac{n(n-1)(n-2)}{3!}a^3x^{n-3} + \ldots a^n$$

Where $2!$ means 1×2, $3!$ means $1 \times 2 \times 3$, etc.

A particular case of this series is when $x = 1$, $a = \frac{1}{n}$ and n is taken infinitely large. The expression $\left(1+\frac{1}{n}\right)^n$ is not unity, but has the value

$$e = 1 + 1 + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \cdots$$

This is the base of the natural system of logarithms and is numerically equal to 2.718282 +.

Taylor's Series. — Let $f(x)$ be any function of x, and for brevity write

$$f'(x) \text{ for } \frac{df(x)}{dx}, \quad f''(x) \text{ for } \frac{d^2f(x)}{dx^2}, \text{ etc.}$$

Then
$$f(x+h) = f(x) + hf'(x) + \frac{h^2}{2!}f''(x) + \frac{h^3}{3!}f'''(x) +, \text{ etc.}$$

This expression is known as Taylor's series. Such a series is a useful expression for $f(x+h)$ only when the terms of the higher order are negligibly small, in which case the series is said to be convergent.

Maclaurin's Series is the special case of Taylor's Series when the x in the latter is taken equal to o and the h in the latter is put equal to x. In this case

$$f(x) = f(o) + xf'(o) + \frac{x^2}{2!}f''(o) + \frac{x^3}{3!}f'''(o) +, \text{ etc.}$$

Where by $f(o)$ is meant the value of $f(x)$ for $x = o$, by $f'(o)$ is meant the value of $f'(x)$ when $x = o$, etc.

The following are useful expressions derived from the above relations:

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \text{etc.}$$

$$\log(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \text{etc.}$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \text{etc.}$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \text{etc.}$$

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \text{etc.}$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \text{etc.}$$

[W. A. Del Mar.]

SHAFTING. — (*See also Bearings; Belts and Belting.*) Ordinary shafting for mill work is usually made of solid steel rods, although hollow shafting is sometimes used.

Diameter of Shaft. — The proper size of shafting to use to transmit a given amount of power may be expressed by the formula

$$d = \sqrt[3]{\frac{CP}{N}},$$

where d is the diameter in inches, P the horse-power transmitted, N the speed in revolutions per minute, and C a constant depending upon the desired factor of safety, the number and location of pulleys or gears, the weight of pulleys or gears and belting, etc. Various authorities assign different values to C, ranging from 40 to 125, the lower value for short shafts used simply for transmitting power, a higher value for line shafts (carrying several pulleys), and the highest value for head shafts carrying the main driving pulley.

Distance Between Bearings. — The distance between bearings may be expressed by the formula

$$L = \sqrt[3]{Bd^2},$$

where L is in feet, d in inches and B is a constant dependent upon the elasticity of the shaft, the load on the shaft and the allowable deflection. The latter is usually taken as 1/100 of an inch per foot of length. The Pencoyd Iron Works take $B = 720$ for bare shafts, and $B = 140$ for shafts carrying pulleys.

Speed of Shafting. — The following represents average practice.

Machine shops	120–240 revolutions per minute.
Wood-working	250–300 revolutions per minute.
Cotton and woolen mills	300–400 revolutions per minute.

BIBLIOGRAPHY. — See Kent's *Mechanical Engineers' Pocket-Book* and the various works on *Machine Design* listed in the Bibliography at the end of article on *Bearings*.

[Wm. Kent.]

SHOCK, ELECTRIC. — The physiological effects of a shock by lightning or by artificially-produced electricity may be classified into two groups: the major effects, cessation of respiration or heart action and the minor effects, fractures and internal injuries due to falls, and burns due to contact with electric arcs.

Removal of Victim from Circuit. — If a switch or circuit breaker in the circuit is close at hand, open the circuit at once or cut away the conductors with a wooden-handled hatchet. If the circuit cannot be opened immediately, break the contact of the victim with the conductor by moving the conductor or the victim, using any available dry non-conductor such as a board, rope or clothing. *Do not touch the victim with the bare hands under any circumstances unless insulated thoroughly from the ground.*

First Aid for Slight Shock. — If the victim is seen to be breathing, administer heart stimulants such as alcohol, ether or ammonia either by the mouth or hyperdermically, produce external warmth by rubbing the body or by application of hot substance, loosen constricting clothing about the neck and chest and present aromatic spirits to the nostrils to excite consciousness. Give plenty of fresh air.

Artificial Respiration. — If the victim does not breathe, send for the nearest doctor, remove any foreign body (tobacco, gum, false teeth, etc.) from his mouth and throat and begin artificial respiration at once, even if the victim appears to be dead. Proceed as follows:*

(*a*) Lay the subject on his belly, with arms extended as straightforward as possible and with face to one side, so that nose and mouth are free for breathing; see Fig. 1. Let an assistant draw forward the subject's tongue.

Fig. 1.

(*b*) Kneel, straddling the subject's thighs and facing his head: rest the palms of your hands on the loins (on the muscles of the small of the back), with fingers spread over the lowest ribs, as in Fig. 1.

(*c*) With arms held straight swing forward slowly so that the weight of your body is gradually but not violently brought to bear upon the subject, see Fig. 2. This act should take from two to three seconds. Immediately swing backward so as to remove the pressure, thus returning to the position shown in Fig. 1.

* Report of Commission on Resuscitation from Electric Shock issued by National Electric Light Association.

(*d*) Repeat deliberately twelve to fifteen times a minute the swinging forward and back — a complete respiration in four or five seconds.

(*e*) As soon as this artificial respiration has been started, and while it is being

Fig. 2.

continued, an assistant should loosen any tight clothing about the subject's neck, chest or waist.

(*f*) *Continue the artificial respiration, if necessary at least an hour, without interruption,* until natural breathing is restored, or until a physician arrives. If natural breathing stops after being restored, use artificial respiration again.

(*g*) Do not give any liquid by mouth until the subject is fully conscious.

Other Methods of Inducing Respiration are: (1) withdraw the tongue and allow it to recede periodically, the whole manipulation occurring about fifteen times in a minute; (2) dash cold water upon the face; (3) rub spine with ice; (4) massage chest in region of heart; and (5) administer oxygen gas (obtained at drug stores) by placing cone over mouth and nose.

After Treatment. — After the victim breathes again, treatment may be administered as outlined above in the case of a slight shock. If any bones have been fractured or if the victim appears to have received internal injuries, do not move the victim any more than is necessary and prepare for removal to the nearest hospital.

Treatment of Burns and Blisters. — If the victim has received burns, raw or blistered surfaces should be protected from the air. Blisters should not be opened. Cut around any clothing that sticks and saturate the adhering cloth or cotton dressing with picric acid (0.5 per cent) or a solution of baking soda (one teaspoonful to a pint of water). Wounds may be coated with a paste of flour and water or may be protected with machine, transformer, linseed or olive oil or vaseline. The dressing should be covered with cotton, gauze, lint, clean waste or clean handkerchiefs held tightly in place by bandages. Oil should not be applied to dry charred burns, a light, dry bandage being preferable.

Indication of Death. — Efforts to revive the victim should not cease until death is indicated by the following appearances:* "complete cessation of breathing and heart action, eyelids half-closed and pupils dilated, jaws clenched, tongue appearing between teeth with frothy mucus about mouth and nostrils, fingers semi-contracted with increasing coldness and pallor of surface."

[R. G. Hudson.]

* J. A. Austin, M.D., *Manual of First Aid.*

SHOVELS, ELECTRICAL OPERATION OF. — (*See also Cranes; Motors, Industrial Applications of.*) The operating cycle of an electrically-operated shovel is about 20 seconds, the component times being: hoist 8 to 10 seconds, thrust 10 seconds and swing 10 to 12 seconds, the thrust being in operation at the same time as the hoist and swing are operating. The motors to meet these requirements must have a sufficiently low armature inertia to permit of rapid acceleration under small power, and are therefore generally of the crane or mill-type construction.

Hoist Motors. — In the case of the hoist, considerable advantage may be gained in this respect by using two motors of one-half the capacity each instead of one motor of the full capacity, as the power required for accelerating is much less. For example: Assume a shovel that requires a 225-horse-power, 514 r.p.m. motor for the hoisting operation. Such a motor requires 144 horse-power seconds for bringing up to full speed, whereas if two 115-horse-power, 600 r.p.m. motors are substituted in its place, each motor requiring 63.5 horse-power seconds or both 127 horse-power seconds to bring up to speed, there would be a saving of about 12 per cent in the power required to accelerate the motor alone. On the other hand, such an arrangement may require the use of bevel gears and additional shafting.

Swing Motor. — This motor, although not subject to the severe overloads and shocks encountered on the hoist motors, is subject to frequent reversals, and, as rapid acceleration is required, a motor of similar design as for the hoist should be used.

Thrust Motor. — This motor differs somewhat in its operation in that it is practically stalled during the digging operation, although it may revolve or overhaul according to conditions, and is operated at full speed only after the hoist operation is completed. Its duty is to keep the dipper against the bank, and it must therefore stand still and exert torque most of the time. For this reason its design should be very rugged, and the motor should be able to develop a heavy torque for short intervals of time while standing still, or rotating very slowly.

Location of Motors. — The hoist and swinging motors are as a rule located on the car and are geared to the drums through suitable reducing gears, while the thrust motor as a rule is mounted directly on the boom and communicates its motion to the bucket staff through reducing gears connected to a pinion engaging a rack on the staff.

Type and Size of Motors. — The motor equipments may be either of the direct- or alternating-current type. The direct-current series motor has ideal characteristics for this class of service, but it requires the use of a motor-generator set when only an alternating-current supply is available. With the ordinary phase-wound induction motor it is not possible to obtain the maximum torque at starting and it may therefore be necessary to use a motor slightly larger than what would have been the case with direct current to obtain the same result. It may be possible that alternating-current commutator motors may find a useful field in connection with this service, although the objection to the single-phase type would be the heavy unbalancing effect on the system, especially at the beginning of each operating cycle, i.e., when the hoist and thrust motors are being started.

The approximate size of motors required for the various operations of a number of different size shovels may be obtained from the following table:

Control Equipment. — The magnetic contactor control is preferable for all the motors on the shovel. (*See Controllers.*) The hoist and thrust motors are then provided with a notching-back arrangement which will automatically cut

Weight of shovel in tons	Size of dipper in cubic yards	Average cycles of operation per minute	Horse power of motors		
			Hoist	Thrust	Swing
135	6	2	150	75	75
120	5	2	150	50	50
105	4	2	150	50	50
95	3¼	2¼	100	50	50
80	2½	2½	100	30	30
65	2	2¾	60	30	30
45	1½	3	60	20	20
25	¾	3½	40	20	20

resistance into the circuit when the current exceeds a certain limiting value due to the motors becoming stalled by digging too deep or striking rocks or other obstructions, thus protecting the motors from damage. Sometimes the hoist and swing motors are provided with automatic magnet control while the thrust motor is hand controlled, an ordinary drum controller being provided for this motor.

Brakes for the different shovel motions are generally of the air-brake type, a small air compressor being provided on the shovel for this purpose.

[D. B. Rushmore, assisted by E. A. Lof.]

SHUNTS. — (*See also Ammeters; Galvanometers; Voltmeters; Wattmeters.*) When heavy currents are to be measured it is impracticable in many cases to pass the entire current through the coils of the instrument proper. In such cases it is necessary therefore to pass the bulk of the current through a parallel circuit or shunt and measure only a known fraction of the total current.

CONSTRUCTION. — For laboratory work standard resistance units (*see Resistors, Standard*) are commonly employed as shunts when a high degree of precision is required. Special forms of resistance boxes, usually called shunt boxes, are also used. For switchboard work shunts made of sheets of manganin or other high-resistance metal of low temperature coefficient (*see Wires, Resistance*) are usually employed. Several sheets of metal are used in order to provide a large radiating surface. These sheets are brazed into heavy copper terminals for clamping to the bus-bars or other heavy conductors; heavy terminals are necessary to insure a uniform distribution of current in the sheets. The contact surfaces must be kept bright and the bolts tight.

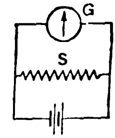

Fig. 1. Galvanometer and Shunt

THEORY OF SHUNTS. — Fig. 1 shows diagrammatically a simple shunt such as used with an ammeter or galvanometer. The galvanometer (or ammeter) current is

$$I_G = \frac{S}{G+S} \cdot I_B,$$

where G and S are the resistances of galvanometer and shunt respectively and I_B is the total current from the battery or other source.

For example, if the galvanometer has a resistance of 9900 ohms and the shunt a resistance of 100 ohms, the galvanometer current will be 1/100 of the battery current. Shunt boxes made on this principle are usually provided with resistance coils giving a ratio of currents of 1/10, 1/100 and 1/1000 when used with a galvanometer having a given resistance. The corresponding readings of the ammeter or galvanometer, multiplied by 10, 100, 1000, or 10,000 will then give the current in the battery circuit.

"Universal" Galvanometer Shunts. — Simple shunts such as above described give even ratios of currents only when used with a galvanometer of a certain definite resistance. A set of coils arranged as shown in Fig. 2, when used as described below, will give even ratios when used with a galvanometer of any resistance. A shunt of this kind is known as a universal shunt. The Ayrton and Mather shunt is arranged on this principle.

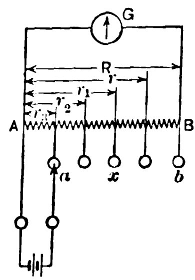

Fig. 2. Diagram of Ayrton and Mather Universal Shunt

A study of the circuits will show that if the galvanometer is calibrated (*see Galvanometers*) with the terminal a at b, that is, with all the resistance R in parallel with the galvanometer, the same calibration may be used for a connected to any other terminal x, provided the current values from the calibration curve are multiplied by the ratio R/r_x, where r_x is the resistance in the box between that terminal and A. The various resistances are usually arranged so that these ratios or "multiplying powers" of 10, 100, 1000, and 10,000 may be obtained. The galvanometer should have a relatively low resistance compared with the total resistance of the shunt.

Effect of Temperature Changes. — The resistivity temperature coefficient of a shunt made of manganin is very much lower than the temperature coefficient of the copper circuit of the ammeter or galvanometer. Consequently changes in temperature will produce a change in the relative resistances of the shunt and ammeter or galvanometer, thus changing the multiplying power. For accurate measurements a correction should therefore be made in the nominal multiplying power of the shunt. With a universal shunt and a relatively low-resistance galvanometer the effect of temperature changes is less marked, since the resistances r_x and R are both in the same box and are usually made of manganin or other metal having a low temperature coefficient.

COSTS. — A 4-coil laboratory shunt box for use with an ordinary galvanometer and giving multiplying ratios of 10, 100, 1000 and 10,000 costs about $20. Switchboard shunts cost from $3 to $90 depending upon their current-carrying capacity, the lower figure applying to a 10-ampere shunt and the higher figure to a 10,000-ampere shunt.

[H. Pender and H. R. Rankin.]

SIGNALING, RAILWAY. — Railway signaling is the art of conveying information to the person or persons in immediate charge of the movement of a train. The means for conveying the information are various, including simple movements of the hands or arms and more or less complicated combinations of positions of semaphore arms by day, or colored lights by night.

CARDINAL PRINCIPLE OF RAILWAY SIGNALING. — The cardinal principle of design of all signal circuits, apparatus and systems, is that any failure of any part, such as breaks, open or short circuits, grounds, etc., if having any effect on the signal whatever, shall result in a stop indication.

CLASSIFICATION OF SIGNALING SYSTEMS. — The two main divisions of railway signaling are block signaling and interlocking signaling. The former has to do with keeping trains which are running on the same track properly spaced. The latter has to do with the handling of trains over tracks which intersect at points of crossing or divergence, and has for its object the prevention of conflicting movements, the proper routing of trains, and the insurance that the movable parts of the track are in their right positions before the signals governing movement over them can be made to give a proceed indication.

Block signals may be divided into two main classes: non-automatic and automatic. In the United States there are 71,469 miles of track protected by the former as against 36,943 miles of track protected by the latter. Of the non-automatic blocks, those on 70,493 miles of track are operated by telegraph or telephone.*

NON-AUTOMATIC BLOCK SIGNALING. — Systems in this class are of two kinds, non-controlled and controlled.

Non-controlled Manually Operated System. — The manually-operated signals used in connection with the telephone or telegraph blocks are located at passenger stations, junctions or other convenient points where operators are available. They are put in the proceed position to permit a train to enter the next block provided information has been received by the operator from the next station in the direction of traffic that the preceding train has passed out of the block. They are placed in the stop position on the passage of the train.

The operators have blanks on which they enter the designation numbers of each train they admit to a block, together with the time of entrance. On the same sheet is checked off the departure of the train from the block as advised by the operator at the leaving end of the block. The train despatcher, located at some central point, is also kept informed of all train movements, so that in case the schedule is deranged for any cause he can give the necessary orders to expedite traffic, such as changing orders for passing points and giving superior rights to certain trains.

Defects of Non-controlled Manually Operated System. — The defects of the system are obvious, as misunderstandings may arise between operators, trains may be checked off by mistake as having left a block when such is not the case, or trains may part and the fact not be noted by the block operator because of his failing to note the absence of the tail lights carried by the rear car of a train when the first division passes his station.

Controlled Manually Operated System. — These defects are partially overcome by the use of controlled manual block signals. In such systems electric locks are applied to the levers operating the manual signals. The locks are included in circuits running between block stations, and so arranged that when an operator wishes to place a signal in the proceed position he has

* From tables compiled by the Interstate Commerce Commission, January 1, 1914.

first to ask (by bell signal or otherwise) for an unlock from the next station in the direction of traffic, and coöperate with the operator at that station in the proper manipulation of the circuits to get his unlock. A further check on the operators is sometimes obtained by the use of track circuits at the stations to effect a certain degree of control of the apparatus locking the signal levers by the passage of the trains themselves. These systems, however, are all inferior, in the degree of protection given, to the automatic blocks with signals controlled by continuous track circuits, which are described below.

Staff System. — Another form of controlled manual block signal is the staff system in which the possession of a small metal cylinder, or "staff," gives the engineer permission to run through a block. These staffs are normally in one or the other of a pair of instruments called staff instruments, one of a pair being at each end of a block. Only one staff can be taken from a pair of instruments at a time because of their locking features, controlled by circuits between the instruments, requiring the coöperation of two people, one at each instrument, to abstract a staff. Until this staff is replaced in one or the other instrument, no other staff can be withdrawn. Following movements with more than one train in the block can be accomplished by using a divisible staff, made in several sections which must be screwed together in a specified order to permit the insertion of the staff in an instrument when the last train has brought the remainder of the staff through the block.

There is also an automatic staff system in which the coöperation of the second person is not required.

There are about 508 miles of track equipped with the staff system in the United States.*

AUTOMATIC BLOCK SIGNALING. — This subject will be treated under three main headings, in the order stated: Track Circuit, Signals and Their Mechanisms, and Location of Block Signals.

TRACK CIRCUIT FOR AUTOMATIC BLOCK SIGNALS. — The standard means of control of automatic block signals is the track circuit. It is the safest means known because the control is continuous and reliable.

Steam-road Track Circuit (Fig. 1). — The figure shows the elements of a steam-road track circuit. They are a source of electrical energy, means for limiting the flow of current from the source, a section of the rails of a track

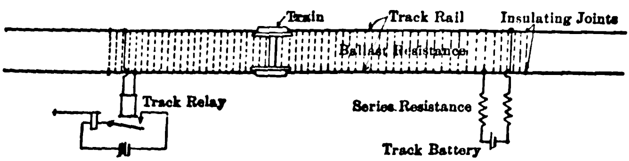

Fig. 1. Elements of a Steam-road Track Circuit

insulated by special rail joints from adjoining rails, the leakage path constituted by the ties and ballast, and an electromagnetic type of relay. The contacts of the relay open and close the circuit which effects the operation of the signal. When there is no train on the track circuit, the contacts of the relay are closed due to the energizing of the relay by current flowing over the rails, which act as conductors from the source of electrical energy. The signal is made to indicate the absence of a train on the track circuit under these conditions. The

* From tables compiled by the Interstate Commerce Commission, January 1, 1913.

presence of a train on the track circuit, or any other cause depriving the relay of energy, causes the relay to open its contacts, which results in the signal taking the stop position. The use of means for limiting the flow of current is to prevent exceeding the capacity of the source when a train shunts the rails, and at the same time to cause such drop of potential across the rails as will insure the opening of the relay.

Electric-road Track Circuit. — The track circuit for a road using electric propulsion, if a direct-current track relay is used, must, in order to avoid false clear signals, have the voltage point at which the relay closes its contacts higher than any voltage which may exist across its terminals, with a train on the track circuit, due to the flow of the propulsion current through the rails. Standard practice, to avoid the possibility of such false closing of the relay contacts, is the use of an alternating-current relay which is not operative to close its contacts under the influence of the propulsion current.

Single-rail Track Circuit (Fig. 2). — Fig. 2 shows an arrangement for d-c. propulsion roads where only one rail is used as the main return for the

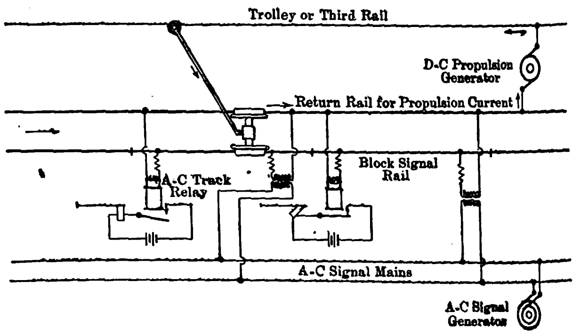

Fig. 2. A-C. Track Circuit, Single-rail System, D-C. Propulsion

propulsion current, the other rail being given up to the signaling current. The resistances used between the rails and the transformer, and between the rails and the relay, limit the flow of propulsion current through those pieces of apparatus. The inductive shunt across the relay serves the same purpose in forming a by-pass for propulsion current. The inductive shunt and the transformer supplying the track circuit have cores with open magnetic circuits to minimize the magnetizing effects of such direct current as may flow through their windings. An arrangement like the above is limited in practical use to those situations where the drop in voltage due to the propulsion current, along the length of continuous rail opposite any section of block rail, is under 50 volts. It finds its greatest application in subway and terminal or interlocking work. Where the number of tracks and shortness of track circuits bring the maximum voltage across the terminals of the relay, due to propulsion current, down to about 5 volts, a relay may be used with resistance enough in its winding to render unnecessary the use of the inductive shunt and resistance between it and the rails.

With a signaling current of higher frequency than the propulsion current and a selective relay, the single-rail track circuit is applicable to a-c. propulsion roads.

Double-rail Track Circuit (Fig. 3). — Where the conductivity of the return propulsion circuit is not sufficient to permit giving up one rail to the signaling current, the arrangement shown in Fig. 3 is used. Both rails are sectioned by insulating joints and the return propulsion current is carried around the insulating joints by means of impedance bonds (i.e., coils having a high inductance and low resistance) which are joined electrically at the middle points of their windings. The flow of the propulsion current is opposed

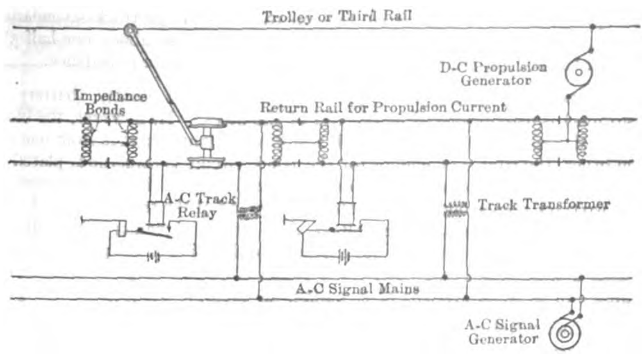

Fig. 3. A-C. Track Circuits, Double-rail System, D-C. Propulsion

only by the ohmic resistance of the bonds and their connections. The full impedance is, however, offered to the flow of the alternating signaling current from rail to rail, and it is, therefore, possible to maintain a difference in potential across the rails sufficient to operate the track relay.

Where the propulsion current is alternating, a higher frequency is used for the track circuit and the relay made correspondingly selective. 25-cycle current is ordinarily used for the signals on direct-current propulsion roads and 60-cycle current on alternating-current propulsion roads.

Source of Energy for Track Circuit. — The source of electrical energy for supplying the track circuit is generally in steam-road practice a gravity battery, in which case no external current-limiting means are necessary. Generally two or three cells are used in multiple, but where the leakage between rails is high, larger numbers are used in series-multiple combinations. Primary batteries of the caustic-potash type are coming into use. The storage battery is used to a limited extent and is especially advantageous on two- or four- track systems where the number of track circuits and amount of apparatus per unit distance is relatively large.

Use of Alternating Current. — Alternating current is rapidly coming into use for signaling on steam roads. Where alternating current is used for track circuits, it is almost universally used to operate the signals and supply the lamps for the night indications. 25- or 60-cycle current is used, the former generally resulting in slightly lower power consumption and being generally favored where the current has to be generated for the signaling system alone and no commercial emergency sources are available. Where such commercial emergency sources *are* available, as is generally the case in thickly-settled districts, the frequency of such sources being ordinarily 60 cycles, that frequency is often chosen for the signaling system.

Transformers for Track Circuits. — The source of alternating current for each block is either a low-voltage (5 to 20 volts) secondary of a transformer

whose primary is connected to the transmission line, or a similar secondary of a small special air-cooled transformer with a 110-volt primary. In the latter case the special transformer may be housed with other signal apparatus and its primary supplied from the 110-volt wires brought from the commercial transformer, whose primary is connected to the transmission line. The same 110-volt wires may be used also to supply the motors, line relays and "hold clear" devices, and carbon lamps used for lighting the signals. If Tungsten lamps are used, they may be supplied from suitable taps on the 110-volt primary of the special transformer or from taps on the low-voltage track secondaries.

Track circuits are generally supplied with current at about one-half the voltage of the source, due to the drop over the intermediate impedance.

Location of Energy Supply.—The source of energy (battery or transformer) is usually placed at the end of the block. If, however, the block is long and impedance bonds are used, resulting in large leakage from one rail to the other, the source of energy for the track circuit is sometimes placed at the center, and the control wires for the signal carried through the contacts of the two track relays, one being located at each end of the track circuit. Under these conditions, because of the voltage drop of the signaling current in the rails, there is only a limited distance extending either side of the point of supply in which a train will shunt both track relays simultaneously. This is taken advantage of in some systems of signaling, an example being given in Fig. 7.

D-C. Track Relay.—The direct-current track relay most commonly used on steam roads has two or four contacts closed when energized, and has a resistance of four ohms. The working voltage across its terminals is generally 0.4 or 0.5 volt under good weather conditions, but may be as low as 0.35 volt during wet weather.

A-C. Track Relay.—There are two types of a-c. track relays called, respectively, "single-energizing circuit type" and "two-energizing circuit type," according to whether they take all of the energy to operate them from the track, or part from the track and part from a local source. These types are built on either one or both of two distinct principles: (1) on the principle of the electrodynamometer (q.v.) and (2) on the principle of the induction motor; (see *Motors, Polyphase Induction* and *Watthour Meters*).

The induction-motor type has the advantage over the electrodynamometer type, in that, its angular motion being unrestricted, a given pressure at the contact points can be produced with a less expenditure of energy. There is a limitation to this, however, due to the friction of the reduction gearing, which must not be so great that it cannot be overcome by the counterweight provided to open the contacts when the relay is deënergized.

With all types of railway signal relays, the addition of "back" contacts to be closed when the relay is deënergized, means the expenditure of more energy to satisfactorily close the "front" contacts, because of the extra counterweighting necessary to develop the necessary pressure on the back contacts.

Single-energizing-circuit Type of Track Relay.—Relays of this type are made on the induction motor principle in order to make them selective between the signal and propulsion currents. The following forms of construction are typical.

(1) Segment of sheet aluminum set in motion by the shifting magnetic field due to the "shaded" pole pieces of a laminated "C"-shaped core which carries the winding. This form is very largely used on short track circuits on d-c. propulsion roads.

(2) Double segment of sheet aluminum acted upon differentially on either side of its axis by the two sets of "shaded" poles of a double "C"-shaped

core. The core is so designed that one or the other set of poles is stronger, depending on the respective amounts of propulsion or signaling current traversing the winding. This form is used on a-c. propulsion roads, being made selective between 25 and 60 cycles, the latter frequency being used for the signaling current.

(3) Centrifuge driven by split-phase induction motor. This form is used on a-c. propulsion roads. It is selective by virtue of the centrifuge being designed not to close the contacts when driven at a speed corresponding to the lower frequency of the propulsion current.

Typical power figures at the working points are as follows:

Form	Frequency	Volt-amperes	Volts*	Power factor	Number of contacts closed when energized
(1)	25	5.0	3.0	0.55	4
....	60	8.5	5.0	0.55	4
(2)	60	20.0	3.1	0.55	2
(3)	60	6.0	2.3	0.70	10

* Track windings of relays.

Two-energizing-circuit Type of Track Relay. — The following forms of construction are typical: (1) Electrodynamometer; used on d-c. propulsion roads and to some extent on steam roads. (2) Induction motor with gearing; the rotor is a cylindrical shell of copper with a stationary laminated core; used on d-c. propulsion roads and very largely on steam roads. (3) Centrifuge driven by induction motor; used on a-c. propulsion roads; see also preceding section.

The local windings of all two-energizing-circuit relays are generally supplied at from 10 to 110 volts The objection to the higher voltage is the small size of wire and consequently greater liability to damage by lightning.

The following typical power figures are for "two-position" relays, i.e., relays with one energized and one deënergized position. Relays which are caused to assume two energized positions by reversals of the current in one of the windings are termed "three-position" relays, and generally require twice as much power in one of the windings as two-position relays.

Form	Frequency	Track			Local		Number of contacts closed when energized
		Volt-amp.	Power factor	Volts	Volt-amp.	Power factor	
(1)	25	0.70	0.90	0.35	36	0.70	4
......	60	1.60	0.80	1.60	33	0.34	4
(2)	25	0.038	0.65	0.15	2.4	0.70	10
......	60	0.024	0.65	0.15	11.0	0.70	10
(3)	60	1.56	0.60	1.3	11.0	1.0	10

The adjustment of the phase relations of the currents in two-energizing circuit relays has to be carefully cared-for in the choice of the impedance used between transformers and rails, and between local windings and the source of energy supply.

Single- Versus Two-circuit Types. — As a track circuit is, from an engineering point of view, nothing but a very inefficient transmission circuit,* track circuits above a certain length can be worked most economically with a two-energizing-circuit type of relay, as the amount of energy transmitted over the rails can be reduced to a certain point by increasing the amount of energy supplied economically to the second winding from a local source. For track circuits below a certain length, however, the energy supplied to the track circuit for the single-energizing-circuit type of relay is less than the total supplied to the track circuit and the local winding of the two-energizing-circuit type.

The above consideration, taken in conjunction with the fact that a relay with one energizing circuit usually is cheaper than one with two energizing circuits, and does not require the installation of a source of energy supply for a local winding, generally points to the choice of the single-energizing-circuit type for track circuits less than 1500 feet in length. On the other hand, as the single energizing circuit type of relay may be falsely energized by current from an adjacent track circuit, due to broken down insulating joints, it does not give the same degree of protection against this failure as the two energizing circuit type, with the source of current supply to adjacent track circuits of opposite instantaneous polarity.

Impedance Bonds. — Impedance bonds are wound with strap copper varying from 57,000 cir. mils for 22,000-volt, 25-cycle propulsion to 220,000 cir. mils for ordinary d-c. 600-volt interurban work, and 800,000 cir. mils for heavy 600-volt d-c. traction work. The corresponding resistances across rails are respectively about 0.014, 0.0014 and 0.00045 ohm. The respective continuous propulsion current per rail ratings are 50, 500 and 1500 amperes. Typical impedance values from rail to rail are respectively 10 ohms at 2 volts and 16 ohms at 9.2 volts, 60 cycles; and 0.3 ohm at 1.5 volts, and 0.18 ohm at 1.5 volts, 25 cycles.

Though the resistance of the connection around an insulating joint formed by an impedance bond may be relatively high as compared with the resistance of the ordinary rail joint bond, the small number of impedance bonds in a system compared to the number of rail joint bonds results in but a very slight percentage increase in the total resistance of the return propulsion circuits.

The impedance bonds for direct-current propulsion roads are provided with an air gap in the magnetic circuit to limit the change in impedance due to unequal amounts of propulsion current flowing in the two halves of the winding. Good practice is to provide for satisfactory operation with a maximum difference equal to 20 per cent of twice the rated capacity per rail, e.g., a 1500 ampere per rail bond should operate satisfactorily with a difference of 600 amperes between the currents in the two rails.

Impedance of Track Circuits. — The table on the following page gives the impedance per 1000 feet of track under various conditions of bonding in common practice and for the values of current commonly used for the energization

* The inefficiency of the track circuit as a transmission line is due to the drop through the current limiting means between the source of energy and the rails (and in the single-rail system between the relay and the rails), the high reactive drop in the rails, the distributed leakage of ballast and ties, and, in the two-rail system, the concentrated leakage through the impedance bonds. The voltage at which the track winding of a relay is designed to operate is selected first, to obtain safe and reliable operation, and second, to obtain as high a degree of efficiency of the track circuit as is permitted by the characteristics of the track circuit. This generally results, with relays taking a comparatively large amount of energy from the track, in higher voltages for track windings of relays used on steam roads than for those used on electric roads, though the total energy put into the track circuit is less in the former than in the latter case.

of the track elements of relays. Where propulsion current is flowing in the rails, the power factor corresponding to the value of the propulsion current should be used to determine the most adverse conditions of drop of potential of signaling current between the point of supply to the track circuit and the relay.

Resistance of Leakage Path. — The resistance of the leakage path between rails in ohms per thousand feet of track varies with the nature of the ballast, the condition of the ties and the weather conditions. Two ohms per thousand feet is a low wet weather value for track with gravel ballast.

In connection with the calculations involving the values of rail impedance given in the table on p. 1267 the following values for resistance of ballast and ties between rails may be used. They are given for ballast clear of the rails.

	Ohms per 1000 feet of track
Wet gravel	3
Dry gravel	6
Wet broken stone	6
Dry broken stone	16

Transmission-Line Voltages. — Transmission-line (between generator and signal transformers) voltages in standard practice vary from 1100 to 4400 volts inclusive, though in some special cases of subway and elevated road work, or where the mains are carried on existing telegraph poles, they may be lower.

SIGNALS AND THEIR MECHANISMS. — Signal indications for block and interlocking work are given in standard railroad practice by semaphores. The semaphore consists of a wood, or enameled steel, blade or arm, fastened at its inner end to a "spectacle." The spectacle is a casting, or combination casting and metal stamping, embodying the hub for the shaft on which the semaphore rotates, and the colored glass roundels which change position before a lamp fitted with a clear lens, to give the night indications corresponding with the positions of the semaphore. The lamp is provided with a long-time oil burner (usually seven days) or incandescent bulbs.

Weight and Torque of Semaphores. — The weight of the semaphore is distributed to give a maximum torque (tending to return the semaphore to the stop position) varying with different types of operating mechanisms from about 30 to 100 pound-feet. As the torque curve is necessarily a sine curve, a spectacle moving through 90° is generally designed to have maximum torque at about 55°.

Spectacles operated manually, which can be pulled to the stop position, may be lighter than those which, in returning to the stop position, have to return parts of the mechanism which cause them to assume the proceed position.

In automatic signals gravity is depended on almost universally to return the signal to stop.

Semaphore Positions and Colors of Lights. — The three fundamental signal indications are:

1. Stop,* 2. Proceed with caution, 3. Proceed. The standard method of giving these indications is in the upper right-hand quadrant as indicated in Fig. 4, the respective positions of the semaphore arm being respectively at 0°, 45°, and 90°. The corresponding colors of the night lights differ with different

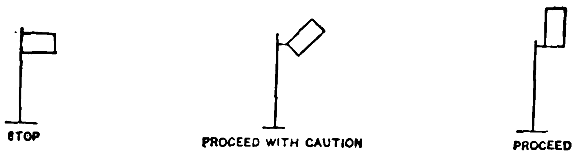

Fig. 4. Standard Semaphore Positions

roads; a common practice is to use red for stop, green for proceed with caution and white for proceed, but on account of the danger of a white light being falsely displayed because of the breakage of the colored roundels it is considered best practice to use red, yellow and green, for the respective indications enumerated above.

It is also good (but less up to date) practice to give these indications in the lower right-hand quadrant, the horizontal position of the semaphore arm always indicating stop. Where the view to the right of the signal mast is obscured, as by the poles along a trolley road, or where clearances are small, due to high walls close to the right-of-way, as through a city, the semaphore is sometimes operated in the upper left-hand quadrant.

Two-position semaphores, indicating stop and proceed only, are also largely used, the proceed indication generally being given at from 60° to 90° depending on the individual road.

Power Mechanisms. — Power signals are operated by "bottom" or "top post" mechanisms. Electricity, compressed air and gas are used as motive power. Of the track mileage protected by automatic semaphores approximately 90 per cent has electrically-operated mechanisms. Compressed gas and air for automatic blocks are limited in use to very few roads, though these include some of the most important ones. The gas is supplied in tanks. The air is distributed in pipe mains.

Electrically-operated Bottom-post Mechanism. — Electric bottom-post mechanisms generally consist of a motor which, by gearing and levers, transmits the movement necessary to clear the semaphore through a vertical rod extending inside the mast between the mechanism and a crank arm on the semaphore shaft. The best types have interposed in the movement transmission system, as near the connection to the vertical rod as possible, an electric latching device called a *slot*. The operation of the semaphore to, and maintenance in, a proceed position depends on this latch being energized, the motor cutting out automatically after performing its work. The location of the *slot* in the movement system close to the vertical rod reduces to a minimum the number of parts moved by the return of the semaphore to the stop position, under the influence of gravity, and, consequently, reduces the possibility of

* An automatic signal in the "stop" position may be passed "according to rule" after bringing train to stop. An interlocking signal in the "stop" position may be passed only after bringing train to stop and receiving authority to pass the stop signal from an authorized person.

the signal sticking in the proceed position due to the development of any friction.

The control of the circuit supplying the motor and slot is effected by the contacts of the track relay.

Electrically-operated Top-post Mechanism. — In top-post mechanisms the motor acts directly on the semaphore shaft through a train of gears. The semaphore in its return to the stop position has to drive the gear train and usually the motor. The ratio of gearing in top-post mechanisms is made comparatively low (about 120 : 1) to diminish friction when going to the stop position, and the motors are consequently very slow speed. The latching of the semaphore in the clear position is accomplished by electromechanical means or by magnetic induction. The latter method obviates the danger of the signal sticking in the proceed position due to the adhesion of contacting surfaces in the latching device.

Power Required for Electrically-operated Signal Mechanisms. — D-c. motors and latching devices are generally supplied with current from local primary or storage batteries at from 8 to 10 volts. With a maximum semaphore torque of between 30 to 50 pound-feet and clearing 90° in about 10 seconds, the motors will consume between 2 and 2½ amperes. The latching device consumes from 0.008 amperes to 0.02 amperes, depending on the voltage and winding resistance.

Under the same conditions as given for d-c. motors, a-c. commutator motors will consume slightly less than 1 ampere at 110 volts at about 0.8 power factor, and induction motors will consume between 2.8 and 3.5 amperes at the same voltage but at about 0.5 power factor.

The electric latching device consumes approximately from 5 to 10 watts in the a-c. mechanisms, the power factor varying widely with the design.

Pneumatically-operated Signal Mechanisms. — The pneumatic mechanism is the simplest of those used for operating signals, consisting of merely a 3-inch by 4-inch cylinder with a metal-packed brass piston, a magnet valve for controlling the admission of air and suitable mechanical connections to the semaphore shaft. The electromagnet valve controlling the admission of air is used as the "slot," as its deënergization shuts off the air and exhausts the cylinder to atmosphere. The pneumatic mechanisms are readily adaptable for bottom- or top-post operation. The air pressure carried varies from 40 to 100 pounds. Ninety pounds is a common pressure.

The advantages of the pneumatic mechanisms are their simplicity, reliability and over-load capacity.

Gas-operated Signal Mechanisms. — The gas-operated mechanisms are similar in principle to those operated by air, but are complicated by the apparatus incidental to the tank supply being at a very much greater pressure than that at which the gas is used in the signal cylinder.

Day-light Signals. — In places where space or view is constricted, powerful light signals are sometimes used to give the day, as well as night, indications in place of the semaphore. Notable examples of this are the New York terminal of the Pennsylvania Railroad, and some of the most modern signal installations on electric interurban roads.

These light signals are generally hooded to make them more visible in sunlight. They are provided with concentrating lenses, and sometimes with specially-constructed reflectors arranged so that light entering from the exterior through the lens will not be reflected out again and give a false indication when the lamp behind the lens is not lighted.

The candle power behind the lens varies from 10 to 120, depending on the

type of lamp and the efficiency of the lenses and reflectors used. The indication given is sufficiently powerful, even in bright sunlight, to permit of the satisfactory operation of high-speed interurban electric cars.

LOCATION OF BLOCK SIGNALS. — Automatic block-signal systems have to take care of such varied fundamental conditions as are found, on the one hand, on single-track roads where the distances between passing sidings may be as great as four miles or more, and the traffic relatively infrequent and, on the other hand, on roads of four tracks, or more, where the traffic is dense, the headway short, and trains of both high- and low-speeds have at times to be handled over parts of the same tracks.

Home and Distant Signals. — The signal at the entrance to a block indicating the presence or absence of a train in that block is called the "home signal." In order that a train may be given warning in time to stop at the entrance to an occupied block, a second signal, called the "distant signal," indicating the position of the home signal at the entrance to the block, is located at a point sufficiently distant to enable the runner to act on the indication and bring his train to a standstill with a reasonable factor of safety before passing the stop signal. This distance will vary with the conditions of grade, curvature of track, and character of train equipment and may be from 3500 to 4200 feet or more.

In three-position signaling the semaphore at the beginning of a block is used to give the home signal for that block and the distant signal for the next block ahead. In two-position signaling the position of the home signal is repeated by a semaphore of distinctive shape, displaying a distinctively-colored light at night. This distant signal may, where the blocks are short, be located on the same mast with the preceding home signal. If the blocks are long and the rules of the road require a train to be immediately brought under control when advance information is received that the home signal is at stop, it is best to avoid loss of time by placing the signal giving the advance information on a separate mast at the proper distance from the home signal. This applies also to three-position signaling.

With distant signals it is, therefore, evident that in order to have following trains run continually under clear signals, they must be separated by a distance equal, at least, to the distance run by the preceding train during the time occupied by the clearing of the home and distant signals plus the length of the intervening block plus the distance between the home and distant signals.

The relations stated above give the basis for the theoretical location of automatic block signals to safely obtain maximum traffic capacity. In practice one

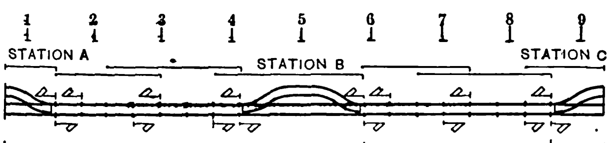

Fig. 5. Arrangement of Single-track Signaling in Both Directions

must consider character of traffic, congested conditions at approaches to terminals, busy passenger stations and junction points, and local conditions such as view and opportunity for suitable foundations, in their effect on signal location.

Arrangement of Signals on Single-track Road. — Fig. 5 shows one arrangement of single-track signaling in both directions used by a large western

system. The horizontal lines terminating at one end opposite signals and at the other end opposite insulating joints (the latter indicated by the short marks across the lines representing the rails) show the extent of track governing each signal by virtue of the track circuit.

Even where the distance between stations (or sidings) is less than a mile, it is important that intermediate home signals be placed between stations (or sidings) in order to prevent a train on the main track at a station from causing possible detention to an incoming train. It will be noticed by reference to the figure that eight signals are used to protect traffic, six between stations, and two within station limits. This number of signals is necessary to adequately protect all traffic and at the same time to insure proper flexibility, since, with this arrangement, trains can move up to the station limits under full protection from both directions, even though the main line may be occupied within these limits. This is because a train in a station affects only the entrance signals, and consequently does not affect approaching traffic on either side of the station, neither does a train on one side of a station influence traffic on the other side.

Fig. 6 shows the circuits for the system shown in Fig. 5.

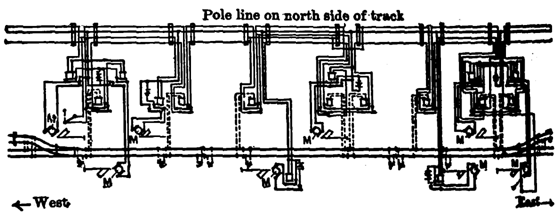

Fig. 6. Circuits for System Shown in Fig. 5

Special Arrangement for Single-track Interurban Road. — Fig. 7 shows a system of signaling which is particularly applicable to interurban single-track signaling where special conditions sometimes render it extremely desirable to

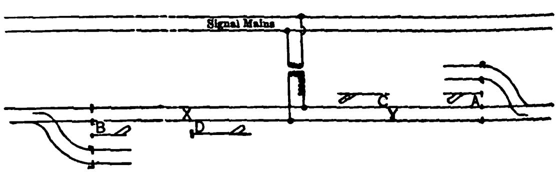

Fig. 7. System for Single-track Interurban

permit more than one car, moving in the same direction, between sidings, and yet give both head-on and rear-end protection.

Because of the impedance of the rails and the characteristics of the voltage supply to the track circuit, track relay at signal "A" is deënergized only by a train between "A" and "X." Similarly, track relay at signal "B" is deënergized only by a train between "B" and "Y." Signals "A" and "B" are connected so that both will go to "stop" on the entrance of a car at either end of the block, but for following cars the signal at the entering end will clear up after

any preceding car has gone half the distance between sidings plus half the distance $X-Y$. $X-Y$ is generally about 3000 feet where distance $A-B$ is about 2 miles. If, by any misunderstanding, cars going in opposite directions should enter a stretch of track between sidings, they would be stopped by signals "C" and "D," located sufficiently far apart to allow for a proper factor of safety in stopping.

Trolley Wheel Operated Signals. — Block signals controlled from a contactor operated by the trolley wheel do not meet the requirements of high-speed signaling as to reliability, and are of value principally in preventing the loss of time due to two cars moving in opposite directions entering the same stretch of track, where conditions of vision and speed are such that there is small chance of harm resulting from a collision.

Arrangement of Signals on Double-track Road. — Fig. 8 shows a typical a-c. automatic block-signaling system with circuits for a two-track road. It will be noted that the *control* of the third position of the signals is obtained by the use of *line wires* running between the signals and supplied with current by circuit controllers operated by the signals.

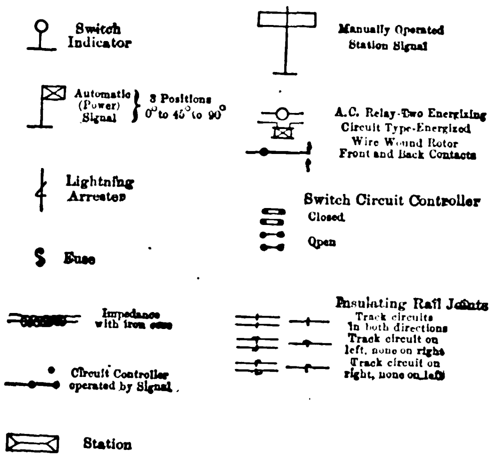

Fig. 8a. Key to Fig. 8

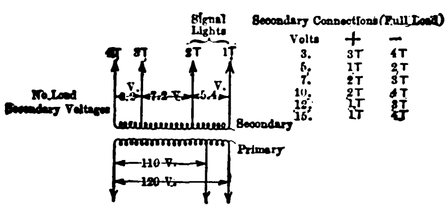

Fig. 8b. Details of Transformer Shown in Fig. 8

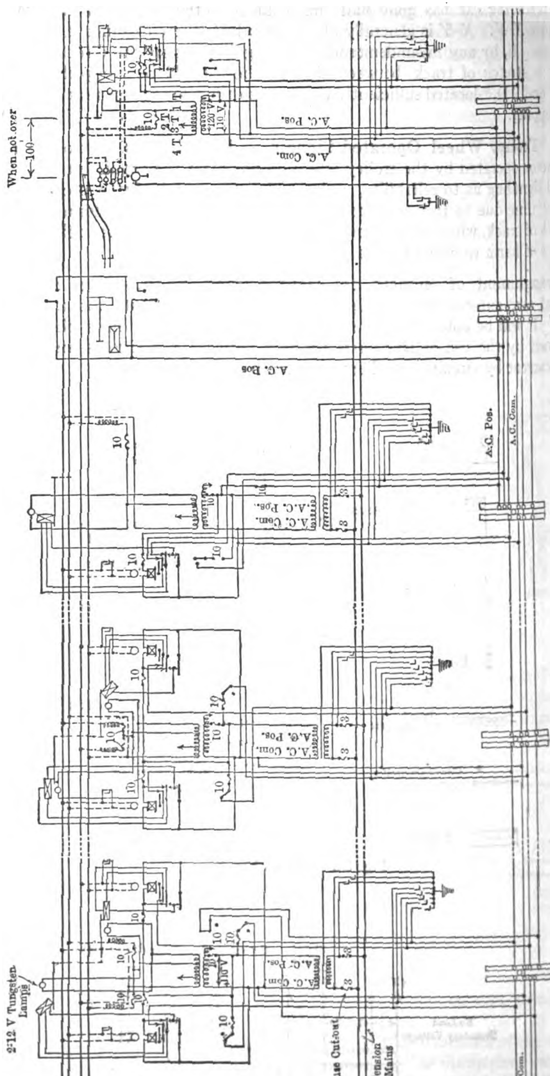

Fig. 8. A-C. Automatic Block System for Double-track Steam Road

The use of two-energizing-circuit track relays as *polarized* relays permits *dispensing* with *control line wires*, in obtaining the control of the third position of three-position signals. The polarized relays close contacts in two positions according to direction of current in track winding and open them when deënergized, as by the presence of a train on the track circuit. The polarity of the current supplied to the track circuit in the rear of any signal depends on the position of that signal and the circuit controllers attached to it. This method is known as *polarized wireless control* and has its counterpart in direct-current signaling.

Maximum Capacity Arrangement. — Fig. 9 shows the latest development of signaling to give maximum capacity where high- and low-speed trains are run on close headway. The main idea is to make possible proper *speed control*. It will be noted that the high-speed trains receive sufficient warning to stop at the proper point in spite of the spacing of signals being made close to get maximum capacity with low-speed trains, which may run for short distances on the high-speed tracks.

Beginning with the first signal behind the occupied block at the left, the indications are respectively "Stop, then proceed according to rule," "Proceed, prepared to stop at next signal," "Proceed, prepared to pass next signal at medium speed," "Proceed."

INTERLOCKINGS AT CROSSINGS, JUNCTIONS AND TERMINALS. — All interlockings are designed with the view of insuring that signals governing traffic over any movable track must be in the stop position before the track parts can be shifted, that the track parts cannot be moved under a train, that they must be locked in the proper position before the signals governing over them can be placed in the proceed position, and that conflicting signals cannot be given.

The apparatus at an "interlocking" consists of the signals and movable

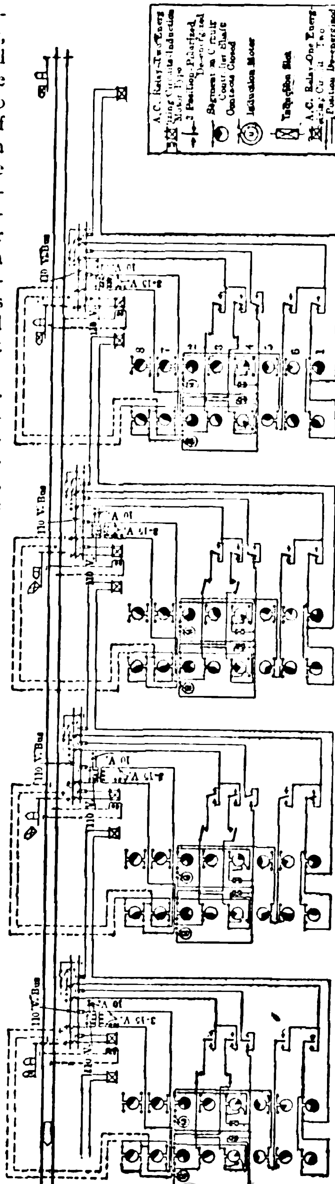

Fig. 9. Circuits of Arrangement to give Maximum Track Capacity

track parts with their operating mechanisms and intermediate apparatus, the central-controlling interlocking machine (sometimes called an "interlocker") located in a signal tower or station, and auxiliary apparatus. Three types* of interlockings are used: (1) mechanical interlocking, in which movement is transmitted to the signals and track parts by means of wire and pipe connections to the levers in the interlocking machine; (2) electric interlocking in which the signals and track parts are moved by electric motors controlled through the interlocking machine; and (3), electro-pneumatic interlocking in which the signals and track parts are moved by compressed air controlled electrically through the interlocking machine. The last two types are called power interlockings as contrasted with the mechanical interlockings.

Almost all large terminals in the United States use electro-pneumatic interlockings. It is most rapid in operation and its simplicity of construction and maintenance, its overload capacity and low voltage give great reliability. In large and busy installations these points are generally considered to overbalance the excess of cost of compressing the air over that of charging the batteries in electric interlockings.

Signal Apparatus.—Interlocking signals differ from automatic signals in external appearance only in such details as are necessary to enable the runner to differentiate them. The differences are generally confined to shapes and markings of arms, locations on masts, etc., and call attention to modifications in the significance of some of the aspects of interlocking signals as distinguished from automatics, e.g., see section above on *Semaphore Positions*. In mechanical interlockings signals are operated by wire or pipe connections to the mechanical levers in the interlocking machine. Sometimes a low voltage electric operating mechanism is used, though the switches remain mechanically operated. In such cases the signals are controlled through contacts operated directly from the mechanical lever or from contacts on a small auxiliary lever properly interlocked with the other levers of the machine.

In power interlockings the signal-operating mechanisms are essentially the same as those used for automatic block signals and are described above in the section on *Power Mechanisms*. Their control and operating circuits replace the mechanically operated pipe and wire connections of the mechanical interlocking signals.

Track Apparatus.—The track apparatus comprises switches, movable point frogs, detector bars, derails, bolt locks, drawbridge locks, etc., with their operating mechanisms.

The detector bar is a piece of steel 3/8 inch or 1/2 inch thick, 2 1/4 inches wide and varying in length up to 55 feet. It is supported beside the head of the rail in the vicinity of a movable part of the track, so that it is capable of vertical motion above the head of the rail when no car is present over it.

On account of the fact that with power interlocking and a wide head of rail a mechanical detector bar is likely to be forced up outside the wheels of a car over a switch, mechanical bars are being supplanted by short track circuits, called detector track circuits, which are utilized to lock the switch-control lever in the interlocking machine against being thrown under a train while a train is over a movable track part.

In all types of interlocking the movable part of the track is locked in position by connecting to it a horizontal bar, called the lock rod, which moves with the track part at right angles to the track. The lock rod is provided with holes

* Combinations of (1) and (2) are rapidly coming into use, and are of great advantage when the tower space is restricted and a change of track layout calls for an increase of capacity over that of the existing "mechanical" machine. The combination ...alled "Electro-mechanical."

or notches into which a bar, moving in guides parallel to the track, may be moved when the switch, or other moving part, is in its correct position. This latter bar, which engages the lock rod, receives its motion from the connection which operates the detector bar. The sequence of movements at the switch is: (1) the lifting of the detector bars; (2) the withdrawal of the bar engaging the lock rod (the latter operation not being capable of completion unless it has been possible to raise the detector bar to the full extent of its travel); (3) the movement of the switch, or other track part; (4) the lowering of the detector bar; (5) the entrance of the locking bar into the hole or notch in the lock rod, provided the moving part has made its full travel and is in its correct position.

Intermediate Apparatus. — The movements enumerated in the above paragraph are generally effected in mechanical interlockings by pipe connections from track parts and their locking devices to corresponding levers in the mechanical interlocking machine. Bell cranks are used in the pipe connections to change the direction of motion. Sometimes all the movements enumerated are effected in proper order by a device located beside the track, called a "switch and lock movement," which may be operated by one pipe connection and machine lever. In power interlockings switch and lock movements are almost always used, power apparatus at the track and electric circuits replacing the mechanically-operated pipe connections.

Power Apparatus for Electric Interlockings. — The power supply for electric interlockings is derived from storage batteries, used in duplicate sets to provide for charging, or in single sets charged while in service or floated on the charging circuit. The nominal voltage is 110, but exceeds this figure if the batteries are charged in operation, or floated, or if, as is sometimes the case, more than 55 cells are used. A 120-ampere-hour cell is a common size for isolated plants. At such plants the charging is generally done two or three times a week by a gas-driven generator. A switch motor operating a single switch without mechanical detector bars in two seconds takes an average current of about 3½ amperes. With about 200 feet of detector bar the corresponding current is about 4½ amperes. A motor signal operating in the same time takes about 2½ amperes to clear and one-tenth ampere to hold. Solenoid dwarf signals, which are quite commonly used, operate almost instantaneously and have a resistance of about 12 ohms and require 0.3 ampere to hold, resistance being cut in when the signal clears.

Power Apparatus for Electro-pneumatic Interlocking. — Each signal cylinder in electro-pneumatic interlocking is provided with an electromagnetic pin valve fastened directly to the cylinder. The piston is metal-packed, single-acting and self-sealing at the end of its stroke under pressure. The cylinder bore is 3 inches and the stroke 4 inches except where two cylinders act jointly to obtain three positions of the semaphore. Admission of air is obtained by the energization of the magnet valve, and exhaust by the deënergization, the piston returning under the influence of the counterweight of the semaphore.

The switch cylinders are double acting, and vary from four inches to seven and one-half inches in diameter, depending on the character of the load, and have a stroke varying from a length equal to the throw of the switch up to 10 inches. The smaller cylinders are used to act directly on the switch points without bars, the larger ones to operate (through the medium of a switch and lock movement) the heavier movable-point frogs in connection with one end of a double slip with their complement of bars. The stroke of the larger cylinders is generally 8 inches. Air is admitted to the cylinder by a slide valve. The latter is shifted by two small single-acting pistons, the admission of air to which is controlled by electromagnetic pin valves similar to those used on the signal cylin-

ders. The slide valve is locked in its extreme positions by a pin actuated by a small piston controlled by a third electromagnet valve whose energization must precede the operation of either of the pistons which shift the slide valve.

The control of the various magnet valves is effected by contacts operated by the interlocking machine levers. Storage battery to give about fourteen volts is generally used and the individual currents may vary from 1/40 to 1/80 of an ampere. From 75 to 100 pounds air pressure is generally carried.

Interlocking Machine for Mechanical Interlocking. — The interlocking machine comprises the levers, or controller handles, corresponding to the apparatus governed, and the mechanical, or mechanical and electrical, interlocking devices between the levers themselves, and between the levers and the apparatus governed by them.

The mechanical locking between levers is effected in the "locking bed." This is an iron plate, with two sets of parallel grooves. One set of grooves contains cold-rolled steel bars of rectangular cross section connected to and moved by the levers. The other set of grooves, at right angles to the first, contains shorter bars with ends shaped to engage with projections or depressions on the bars connected to the levers. The cross bars engage with the lever bars in such a manner that a lever cannot be moved unless the lever bar affecting the other end of the cross bar is in a definite position.

In a mechanical interlocking the operation of the detector bar and locking bar operating in conjunction with a movable track part, is generally effected by a separate lever in the interlocking machine, called the lock lever. This lever is interlocked with the proper signal levers so that the latter must have been operated to put the corresponding signals to stop before the lock lever can be operated to raise the detector bar and unlock the switch. The switch lever is, in turn, interlocked with the lock lever so that if the lock lever cannot make its full stroke, due, for example, to a train being over the detector bars, the switch lever cannot be thrown. If, after the switch lever is thrown, the lock lever cannot be thrown fully back to its original position, due, for example, to the switch not having made full travel, and the locking bar not being able to properly engage the lock rod, the interlocking between the lock and signal levers prevents the latter from being operated to put the signals in the proceed position. In mechanical interlocking plants rods connected to the signals are also often made to engage with the lock rod of the switch.

Further protection is often obtained in mechanical machines by attaching to moving parts connected to the levers circuit controllers and electromagnetic locks. The electric locks act by gravity when deënergized to engage with a moving part connected to the lever. The circuit which energizes them may be carried through circuit controllers attached to the signal or track mechanisms, or through the circuit controllers on other levers.

Interlocking Machine for Power Interlockings. — In power interlockings the levers are small as they have to operate only the mechanical locking in the machine, and contacts for controlling the various circuits. The strain which can be brought on the mechanical locking is thereby reduced, and it is made correspondingly smaller than in mechanical interlocking machines. In these types of machines where the levers give a rotary motion to the circuit controllers it is possible, by the use of the two extreme positions of the levers, to control signals governing over the same route in opposing directions by the same lever. Only circuits for signals in one direction are closed in an extreme position and the indication referred to below being received before the levers can be returned to the middle position, where it releases the mechanical locking, insures against signals being placed in the proceed position if opposing signals controlled by the same lever have not returned to stop.

Depending on the type a power interlocking machine may occupy less than one-quarter of the space taken by a mechanical machine, and require but one-quarter of the operators. Space is also saved on the ground, as the pipe connections and foundations are replaced by wires.

In power interlockings the completion of the stroke of a movable-track part and its proper locking is "indicated" on the machine by the energization of an electromagnetic lock which allows the lever to complete its full stroke, thereby releasing the proper mechanical locking in the machine. The circuit for the lock is carried through contacts on the moving mechanism on the ground. The return of a signal to the stop position is indicated in a similar manner.

Control of Current for Electric Interlockings. — The supply of current to the signals, switches, etc., may be effected directly by the controller in the interlocking machine, or by simple or polarized secondary controllers located at the various signals and switches, the windings of the secondary controllers being in turn supplied in whole or in part with current from the machine's lever contacts. The use of the secondary controllers permits the wires between them and the interlocking machine to be small, the power for operating the signals, switches, etc., being supplied through contacts operated by the secondary controller from mains running through the plant.

On account of the small amount of current used to operate the secondary controllers, compared to the amount used by the apparatus they supply, the contacts in the interlocking machine may be as small and compact as in an electro-pneumatic interlocking machine, and therefore offer the same excellent opportunity for intercontrol of circuits in the machine itself. This is particularly important, for instance, where it is desired to effect *route locking* (see below), where it may be necessary to have certain signals and switches enter into a great variety of combinations.

Indication Current for Power Interlockings. — Among the various methods of providing the current for "indication" may be mentioned: (1) the use of the same current as is used for control and operation, called "battery indication;" (2) the use of polarized apparatus in connection with the preceding, or in connection with current of a different character from the operating current, to reduce the chances of false indications due to crosses, grounds, etc.; (3) utilization of the momentum of the operating electric motor to generate the indication current after the motor has completed the movement of the apparatus; (4) the operation of the electric motor as a motor generator after it has completed the movement of the apparatus, the generated current being distinctive in character, viz., alternating or of greater voltage than the operating current and of such direction as to selectively operate polarized magnets.

Auxiliary Apparatus. — Various relays, indicators, annunciaters, emergency time lever releases and special circuits are used in connection with or in addition to the essential interlocking apparatus to expedite the handling of traffic and to meet special conditions.

Approach Locking. — Where electric locking is effective while a train is approaching a signal which has been set for it to proceed, to prevent manipulation of levers or devices which would endanger that train, it is termed *approach locking.*

Route Locking. — When electric locking is so arranged that it takes effect when a train passes a signal to prevent manipulation of levers which would endanger the train while it is within the limits of the route entered, it is termed *route locking.*

Sectional Route Locking. — To minimize the limitation of trackage capacity which results from route locking, especially when the route lies across the through tracks, *sectional route locking* is used. This is route locking so

arranged that a train in clearing each section of a route releases the locking affecting that section. The detector track circuits are used to accomplish this type of locking. When *route locking* is not used it is necessary, in order to safely obtain full trackage capacity, to space the signals so close that no considerable amount of track is locked by the clearing of any one signal. Where the track layout and traffic conditions are such that short switching moves predominate over through routing this latter method is superior in giving greater capacity and flexibility.

AUTOMATIC STOPS. — Automatic stops have been in use for a number of years in connection with elevated and subway roads. They have been operated by direct mechanical connection to the signals or by separate mechanisms working in conjunction with the signals, and have consisted of arms located on the roadbed so that when elevated they were in position to engage with and operate a connection to the brake system on the car. It is evident that as a train may travel a considerable distance after the brakes are applied, and as the engineman or runner is dependent on the signals for the knowledge necessary to the proper control of his train, the relation of signal and stop locations must be such that in case the signals are properly observed the brakes will not be automatically applied, while if the contrary is the case, the space intervening between the train causing the display of the danger signal and the automatic stop protecting it must be sufficient to allow a following train being brought to rest without a collision.

This may be accomplished in two ways: (1) by using an overlap (i.e., extending the control of a signal to a point sufficiently beyond the next succeeding signal), which increases the spacing of trains and diminishes the capacity of the road; (2) by giving the runner an advance indication of the position of the signal at which it may be necessary to make a stop, so that if necessary he may bring his train under control in time to stop at the proper point. In the latter case the automatic stop is located to bring the train to rest at the stop signal, in case the speed has not been properly reduced. Up to the present (1913) automatic stop installations have been almost universally on the overlap system.

On account of clearances and atmospheric conditions, the automatic stop problem for steam roads is very difficult of solution. The problem is further complicated by the fact that there are involved the different conditions affecting freight and passenger traffic, a differentiation between the absolute stop indication of an interlocking signal and the permissive stop indication of an automatic block signal, and a differentiation between the speeds permissable over different routes, as indicated by an interlocking signal, with two or more arms, located at a point of divergence.

The above considerations indicate that the satisfactory solution of the automatic-stop problem for the majority of roads must follow the trend of modern signaling, and be based on speed control.

SKIN EFFECT. — (*See also Electricity and Magnetism, Principles of; Resistance and Conductance, Electric.*) A conductor of finite cross-section may be looked upon as made up of separate filaments, just as a beam may be looked upon as made up of separate fibers. The inductances of the various filaments which make up such a conductor are different, due to the fact that the exterior filaments are linked by fewer flux lines than the interior filaments; see *Electricity and Magnetism, Principles of,* and *Inductance and Inductive Reactance.* Consequently, when the same potential gradient (varying with time, however) is established through all the filaments of such a conductor, by connecting it to some external source of alternating or varying e.m.f., the self-induced back e.m.f. in the interior filaments will be greater than in those filaments nearer the surface, and therefore the resistance drop in the interior filaments must be less than in the surface filaments. This can be brought about only by the current distributing itself over the cross-section of the conductor in such a manner that the current density in the interior of the wire will be less than at the surface, i.e., the current is forced toward the surface filaments or "skin" of the wire; hence the term "skin-effect" for this phenomenon.

Factors upon which the Skin Effect Depends. — The self-induced e.m.f. depends not only upon the amount of flux set up but also upon the rapidity of its variation; hence the skin effect becomes more pronounced the greater the frequency of the impressed e.m.f. It is also greater the larger the cross section of the conductor, the greater the conductivity of the conductor and the greater its magnetic permeability. It also depends slightly upon temperature since the conductivity changes with temperature.

Change in Resistance and Inductance due to Skin Effect. — As a consequence of the skin-effect the effective resistance of a conductor to alternating currents is greater than to direct currents, but the *internal* inductance *decreases* with the frequency; the external inductance is not altered; see *Inductance and Inductive Reactance.* Whereas, however, the internal inductance with increasing frequency approaches a limiting value, the resistance increases indefinitely as the frequency approaches an infinite value. The change of resistance is always relatively much larger than the change in the total inductance.

The effects just described are, for the most part, negligible at low frequencies, except in the case of heavy conductors and in coils wound with stout wire in several layers. In the latter case, however, the diminution of the inductance, due to the irregular distribution of the current, is masked, to a greater or less degree, by the effect of the capacity between the windings of the coil, which gives rise to an *increase* of the inductance with the frequency. For the same reason the resistance is increased more than it would be by the eddy currents alone.

Unfortunately, the rigorous or approximate solution of the problem at high frequencies for the various cases which arise in practice is in many instances very difficult, if not impossible.

SKIN EFFECT IN STRAIGHT ROUND WIRES. — An accurate solution for the case of straight *solid** wires of circular cross-section has been given in a number of different forms by various scientists. A summary of the formulas is given in a paper by Rosa and Grover, *Bull. Bur. Stds., 1912, Vol. 8, p. 172.* The calculations are most conveniently made by the use of the

* Tests at the Massachusetts Institute of Technology in 1913 indicate that the formulas for solid wires also apply to round *stranded* wires of the *same cross section of metal,* not the same over-all diameter.

tables given in Rosa and Grover's paper, which are given in a condensed form below. Let

f = frequency in cycles per second,
μ = permeability of the wire, *assumed constant,*
R = direct-current resistance, in ohms, of 1000 feet of the wire; see tables in the article on *Wires and Cables, Bare.*
L = direct-current inductance, in millihenries per 1000 feet, of a *non-magnetic* wire of the same *cross section* as that of the given wire, and at the given spacing between wires, taken from the tables in the article on *Inductance and Inductive Reactance.*

Calculate the quantity

$$x = 0.02768\sqrt{\frac{\mu f}{R}}, \tag{1}$$

and take from the following table the corresponding values of K_1 and K_2. Then the alternating-current resistance at the frequency f is

$$R' = K_1 R \qquad \text{ohms per 1000 ft.} \tag{2}$$

and the alternating-current inductance of the given wire at the frequency f is

$$L' = L + 0.01524\,(\mu K_2 - 1) \qquad \text{millihenries per 1000 ft.} \tag{3}$$

For x greater than 7 the following relations hold to within less than 1 per cent, the error being less the greater the value of x:

$$R' = \left(\frac{x}{2.828} + 0.25\right)R, \tag{4}$$

$$L' = L + 0.01524\left(\frac{2.828\,\mu}{x} - 1\right). \tag{5}$$

Example.—Take the case of a 1,000,000-circular-mil copper cable (assumed equivalent to a solid wire of the same cross section; see footnote on preceding page), frequency 60 cycles, and return wire 10 ft. away. Then at 25° C., R = 0.0108 ohm per 1000 ft. of wire, L = 0.3494 millihenry per 1000 ft., for direct current. The value of x is

$$x = 0.02768\sqrt{\frac{1 \times 60}{0.0108}} = 2.06.$$

From the table below K_1 = 1.088 and K_2 = 0.957, and the alternating-current resistance at 25° C. is therefore $R' = 1.088 \times 0.0108 = 0.0118$ ohm per 1000 ft. and the alternating-current inductance is $L' = 0.3494 + 0.01524\,(1 \times 0.957 - 1) = 0.3487$ millihenry per 1000 ft.

SKIN EFFECT IN THIN STRIPS AND TUBES. — The following formulas are exact for a flat strip of infinite width and at an infinite distance from any other conductor carrying a current; they also apply with a close degree of approximation to a strip which has a width of 10 or more times its thickness or to a tube which has a circumference 10 or more times its thickness, provided no other conductor carrying a current is closer than a distance of 10 times the thickness of the strip or tube. In the case of several strips in parallel and close to one another, the ratio of the a-c. to the d-c. resistance (and the same

also applies to the a-c. and d-c. inductance) is something between the ratio which would hold for each strip separately and the ratio which would hold for a single strip having a thickness equal to the total thickness of all the strips. The closer the strips are together the nearer is the true ratio to that which would hold for a strip having the total thickness of all the strips.

Let t = thickness of strip, or *twice* the thickness of the wall of a tube, in centimeters,
w = width of strip or *half* the mean circumference of tube, in centimeters,
l = length of strip or tube in centimeters,
ρ = specific resistance of conductor, in microhms per centimeter cube, at the given temperature,
μ = magnetic permeability of conductor in absolute units,
f = frequency in cycles per second,

$$x = 0.1987\, t \sqrt{\frac{\mu f}{\rho}}.$$

Then d-c. resistance is

$$R = \frac{10^{-6}\rho l}{wt} \text{ ohms.}$$

The d-c. internal * inductance is

$$L_i = 1.047 \times 10^{-6}\, l \frac{\mu t}{w} \text{ millihenries.}$$

The ratio of the a-c. to the d-c. resistance is

$$\frac{R'}{R} = \frac{x}{2}\left(\frac{\sinh x + \sin (57.3\, x)^0}{\cosh x - \cos (57.3\, x)^0}\right)$$

and the ratio of the a-c. to the d-c. internal inductance is

$$\frac{L_i'}{L_i} = \frac{3}{x}\left(\frac{\sinh x - \sin (57.3\, x)^0}{\cosh x - \cos (57.3\, x)^0}\right)$$

For x less than unity these ratios are unity to within 0.6% and 0.2% respectively, i.e., the a-c. resistance is practically equal to the d-c. resistance and the a-c. internal inductance is practically equal to the d-c. internal inductance. For x greater than 6 the following formulas are accurate to within 0.5%:

$$\frac{R'}{R} = \frac{x}{2} \quad \text{and} \quad \frac{L_i'}{L_i} = \frac{3}{x}.$$

To a very rough degree of approximation the skin effect in a conductor of any shaped cross section may be approximated by using the above formulas for a strip, taking for the effective width w one-half the perimeter of the section (in centimeters) and for its effective thickness twice the area of the section (in square centimeters) divided by its perimeter. In general, then, for the same area the skin effect will be less the greater the perimeter of the section. If the section approaches more nearly that of a solid circle than that of an elongated rectangle, the formulas for a solid round wire will give more accurate results.

SKIN EFFECT IN IRON AND STEEL CONDUCTORS.—The skin effect in conductors having a variable permeability is not susceptible of mathematical calculation. For tests on iron and steel conductors of square section, rails, etc., see report of the International Railway Test Commission, St. Louis,

* The external inductance, which is uninfluenced by the skin effect, depends upon the distance away of the return conductor; see *Inductance and Inductive Reactance.*

1903; as the permeability of iron and steel ranges between such wide limits, the data given in this report should be used with caution. See also the article in this book on *Trolley Systems, Overhead; Signalling, Railway.*

Skin Effect in Copper-clad Steel Wires. — The data given below are from tests made in the Electrical Engineering Research Laboratory of the Massachusetts Institute of Technology, on samples furnished by the Duplex Metals Co.

* Approximate.

† Calling L the inductance of a solid round, non-magnetic wire of the same cross section and on the given spacing, taken from the tables in the article on *Inductance and Inductive Reactance*, the alternating-current inductance of the copper-clad wire on this spacing, is

$$L' = L + \Delta L \qquad \text{millihenries per 1000 ft.}$$

BIBLIOGRAPHY. — A complete bibliography on the formulas for skin effect is given in the paper by Rosa and Grover, *Bull. Bur. Stand.*, 1912, Vol. 8, p. 172; see also Steinmetz, C. P., *Transient Electrical Phenomena and Oscillations*, N. Y., 1909.

[H. Pender.]

SMOKE PREVENTION. — The direct cause of smoke from boiler furnaces is that the gases distilled from the coal are not completely burned in the furnace before coming in contact with the surface of the boiler, which chills them below the temperature of ignition.

Smoke may be prevented from forming if each particle of gas, as it is made by distillation from coal, is immediately mixed thoroughly with hot air. Even if smoke is formed by the absence of conditions for preventing it, it may afterwards be burned if it is thoroughly mixed with air at a sufficiently-high temperature. It is easy to burn smoke when it is made in small quantities, but when made in great volumes it is difficult to get the hot air mixed with it unless special apparatus is used. In boiler firing the formation of smoke must be prevented, as the conditions do not usually permit of its being burned.

Essential Conditions. — The essential conditions for preventing smoke in boiler fires may be enumerated as follows:

1. The gases must be distilled from the coal at a uniform rate.
2. The gases, when distilled, must be brought into intimate mixture with sufficient hot air to burn them completely.
3. The mixing should be done in a fire-brick chamber.
4. The gases should not be allowed to touch the comparatively-cold surfaces of the boiler until they are completely burned. This means that the gases shall have sufficient space and time in which to burn before they are allowed to come in contact with the boiler surface.

Every one of these four conditions is violated in the ordinary method of burning coal under a steam boiler. (1) The coal is fired intermittently and often in large quantities at a time, and the distillation proceeds at so rapid a rate that enough air cannot be introduced into the furnace to burn the gas. (2) The piling of fresh coal on the grate in itself chokes the air supply. (3) The roof of the furnace, or tubes of the boiler, is a cold shell instead of a fire-brick arch, as it should be, and the furnace is not of a sufficient size to allow the gases time and space in which to be thoroughly mixed with the air supply.

Methods of Prevention. — In order to obtain the conditions for preventing smoke it is necessary: (1) That the coal be delivered into the furnace in small quantities at a time. (2) That the draft be sufficient to carry enough air into the furnace to burn the gases as fast as they are distilled. (3) That the air itself be thoroughly heated either by passing through a bed of white-hot coke or by passing through channels in hot brickwork, or by contact with hot fire-brick surfaces. (4) That the gas and the air be brought into the most complete and intimate mixture, so that each particle of carbon in the gas meets before it escapes from the furnace its necessary supply of air. (5) That the flame produced by the burning shall be completely extinguished by the burning of every particle of the carbon into invisible carbon dioxide.

If a white flame touches the surface of a boiler, it is apt to deposit soot and to produce smoke. A white flame itself is the visible evidence of incomplete combustion.

Anthracite Coal. — The first remedy for smoke is to obtain anthracite coal. If this is not commercially practicable, then obtain, if possible, coal with the smallest amount of volatile matter. Coal of from 15 to 25 per cent of volatile matter makes much less smoke than coals containing higher percentage. Provide a proper furnace for burning coal. Any furnace is a proper furnace which secures the conditions named in the preceding paragraphs. Next, compel the firemen to follow instructions concerning the method of firing.

Bituminous Coal. — It is impossible with coal containing over 30 per cent of volatile matter and with a water-tube boiler, with tubes set close to the grate

and vertical gas passages, as in an anthracite setting, to prevent smoke even by the most skillful firing. This style of setting for a water-tube boiler should be absolutely condemned. A Dutch oven setting, or a longitudinal setting with fire-brick baffle walls, is highly recommended as a smoke-preventing furnace but with such a furnace it is necessary to use considerable skill in firing.

Steam Jets and Mechanical Stokers. — Mechanical mixing of the gases and the air by steam jets is sometimes successful in preventing smoke, but it is not a universal preventive, especially when the coal is very high in volatile matter, when the firing is done unskillfully, or when the boiler is being driven beyond its normal capacity. It is essential to have sufficient draft to burn the coal properly and this draft may be obtained either from a chimney or a fan. There is no especial merit in forced draft, except that it enables a larger quantity of coal to be burned and the boiler to be driven harder in case of emergency, and usually the harder the boiler is driven, the more difficult it is to suppress smoke.

Down-draft furnaces and mechanical stokers (q.v.) of many different kinds are successfully used for smoke prevention, and when properly designed and installed and handled skillfully, and usually at a rate not beyond that for which they are designed, prevent all smoke. If these appliances are found giving smoke, it is always due either to overdriving or to unskillful handling. It is necessary, however, that the design of these stokers be suited to the quality of the coal and the quantity to be burned, and great care should be taken to provide a sufficient size of furnace with a fire-brick roof and means of introducing air to make them completely successful.

[WM. KENT.]

SPARK GAP FOR MEASURING HIGH VOLTAGES.—One of the simplest methods of obtaining a measure of the value (maximum value in case of an alternating voltage) of a high voltage is to determine the length of air gap between two electrodes across which the given voltage will just cause a spark to pass. The voltage (maximum value) required to break down such a gap depends upon: 1. the shape and size of the electrodes; 2. the presence of other conductors in the vicinity of the gap; 3. the time of application of the voltage; and 4. upon the temperature and pressure of the air. The dependence of the break-down voltage upon the shape and size of the electrode is due not only to the effect of these factors upon the potential gradient in the gap but also to the fact that the maximum potential gradient at which air breaks down is dependent upon the distribution of the electrostatic field in the gap (*see article on Corona*) and is greater for very short gaps (0.5 cm. or less) than for long gaps.

For the same *maximum* value of the voltage it has been found that the striking distance is independent of the wave shape and frequency, and is the same for direct as for alternating voltages.

Time of Application of Voltage.—Air (and other gases) will stand for a short period of time (i.e., a few seconds) a much larger potential than it will stand for an indefinitely long period of time; this phenomenon is known as dilatation. After a voltage has been applied to a gap for about one minute, the apparent dielectric strength becomes sensibly constant. When measurements must be made with great rapidity, dilatation may be prevented by illuminating the gap by an arc-lamp. This procedure reduces the value of the sparking voltage, but only to a slight extent. (The theory of the action is that the ultra-violet light from the arc-lamp ionizes the air in the gap, thereby enabling the spark to pass at once.)

NEEDLE SPARK GAP.—Steinmetz in 1898 (*Trans. A.I.E.E., Vol. 15, p. 281*) made a careful determination of the voltages required to produce a spark between spherical, cylindrical and pointed (needles) electrodes. Steinmetz concluded that the sparking voltage between needle points (a sine wave of potential being used) was especially constant for any given set of conditions and that after the curve connecting spark potential and distance between needle points had been carefully ascertained, the needle spark gap offered a very valuable means for measuring high voltages. Results obtained under like conditions have checked very well for voltages up to about 100,000. Above this voltage, however, it has been found difficult to duplicate conditions nearly enough for different observers to obtain results which are in agreement.

A.I.E.E. Needle Spark-gap and Spark-over Voltages.—See paragraphs 272 and 274 of the *Standardization Rules of the A.I.E.E.* (q.v.)

Effect of Pressure and Temperature on Needle-gap Voltage.—According to H. J. Ryan (*Trans. A.I.E.E., 1904, Vol. 23, p. 101*), the break-down voltage for a needle gap is proportional to the barometric pressure. The A.I.E.E. table is for normal atmospheric pressure and a correction should therefore be applied when the atmospheric pressure differs appreciably from 29.92 inches (76 cm.). No data on the effect of change of temperature are available; for ordinary ranges of temperature the effect is probably small.

Fisher's Spark Gap.—Fisher (*Trans. Int. Elec. Cong., 1904, Vol. 2, p. 20[illegible]*) has suggested the use of a needle gap with concave disks of about 10-inch diameter placed back of the points, these disks reducing the brush discharge and rendering the readings more consistent. The calibration for such a gap is different from that for two opposing needles; see Fisher's paper. Fisher also found

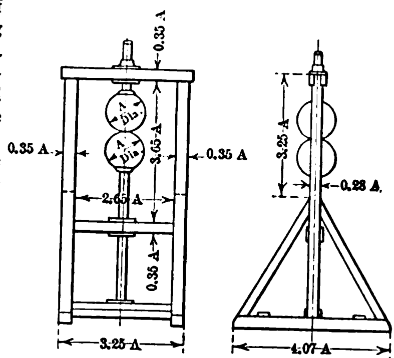
that the degree of sharpness of the needles had a decided effect upon the breakdown voltage, and that the sharper the points the more consistent the results.

SPHERE SPARK GAP. — Farnsworth and Fortescue (*Proc. A.I.E.E., Feb., 1913*) have suggested the use of a spark gap between two spheres. The following is adapted from their paper.

Besides giving inconsistent results the needle-point spark gap is cumbersome and requires a great deal of space. If constructed according to the A.I.E.E. rules, the space required for a spark gap to measure 300,000 volts would be approximately 20 feet by 12 feet by 12 feet as compared with a space of 4 feet by 5 feet by 8 feet required for a sphere spark gap having a range from 50,000 to 412,500 volts. In addition to this advantage the sphere spark gap breaks down with a sharply-defined spark discharge without previous formation of corona, provided the distance of separation is less than the diameter of either sphere. For greater distances of separation the corona forms first and the sparking voltage for a given length of gap becomes more or less variable.

Another advantage of the sphere spark gap is that the terminals do not have to be renewed after each discharge, as is the case with the needle gap.

Construction of Sphere Spark Gap. — Fig. 1 shows the arrangement recommended by Farnsworth and Fortescue and the relative dimensions of the supporting structure in terms of the sphere diameter, A. Being constructed vertically they use a very small floor space as compared with equivalent horizontal needle-point gaps. The top sphere is stationary but slightly adjustable in height so as just to make contact with the lower sphere when it is set for zero separation. The lower sphere is mounted on a piece of brass tubing which carries a threaded bushing on its lower end. This bushing works on a carefully-threaded rod having a pitch of two per centimeter. The bushing being graduated to fiftieths on its circumference, separation may be measured to the nearest 1/100 cm. directly, thus providing a micrometer adjustment. Being made of large parts the whole arrangement is mechanically strong and the spheres are kept in constant alignment. Being mounted on large wheels the spark-gap sets are very portable and may also be picked up by a crane without risk of damage.



Note:- A variation of 1 cm. in thickness and width of wooden parts is permissible.

Fig. 1. Relative Dimensions of Sphere Spark Gap

A.I.E.E. Sphere Spark-gap and Spark-over Voltages. — See paragraphs 272 and 275 of the *Standardization Rules of the A.I.E.E.* (1914 edition).

[W. S. Gorton.]

SPECIFICATIONS AND CONTRACTS. — (*See also Standardization Rules and Standard Specifications; also under name of apparatus.*) Webster defines a specification as a written statement containing a minute description or enumeration of particulars, and a contract as a formal writing which contains the agreement of parties, with the terms and conditions, and which serves as a proof of the obligation. A "preliminary" specification is a description or enumeration of a purchaser's requirements when calling for bids. A "contract" specification is a description or enumeration of labor and material to be supplied under a contract of which the specification is an integral part. A "manufacturer's" specification is a description or enumeration of secondary details peculiar to the work of the individual manufacturer. This also is often made an integral part of a contract.

POLICY TO BE FOLLOWED. — When writing a specification the engineer should bear the following points in mind:

1. A preliminary specification is a commercial instrument designed to describe labor, material or results desired by a purchaser, with the object of enabling competitive bidders to estimate with equal facility upon the amount of a contract.
2. As a rule, contractors are as honest as the struggle for commercial existence permits them to be, and every unnecessary or unfair clause in a specification has its part in limiting competition and lowering the standard of honesty among contractors. A similar remark applies to requirements of which the purchaser cannot ascertain or enforce the fulfillment.
3. The standards of the national engineering societies should be followed unless local conditions prohibit them, and manufacturer's standards should be followed if low bids are to be expected.
4. No specification should contain a blanket clause covering the furnishing of unnamed contingencies unless all bidders are to have an equal opportunity to ascertain what such contingencies are likely to be. If such a clause is made very broad, it is unlikely that the courts would hold it valid.
5. Before drawing the specifications, determine to what extent the contractor is to be made responsible for the final results.
6. Avoid specifying proprietary articles or material as far as possible in order not to restrict competition.
7. Quality is an important factor in cost, hence unless the very best materials and workmanship are required, in spite of the higher cost, it is necessary to adopt some fair commercial standard.
8. There are many minor items in specifications which cannot be minutely described without making the specifications unduly long. In such cases it is good practice to specify that these items shall be made "to the reasonable satisfaction of the inspector," the word "reasonable" saving the contractor from arbitrary and unjustifiable actions of the inspector by enabling him to refer the reasonableness of such actions to the arbitrament of the courts.

FORM OF SPECIFICATIONS. — All specifications should be written in clear, concise language, free from ambiguity, and should be in convenient form for reference purposes.

It is desirable to number the paragraphs or clauses of all specifications to facilitate reference, and every item of the work should be alloted a separate clause.

There are two general classes of specifications. In one class results only are specified and all requirements should be rigorously exact. In the other class details of construction are specified and requirements can be stated in approximate terms only. Wherever practicable the former class of specification should be used. A combination of the two classes is also commonly adopted, but i

such cases an agreement as to results does not bind the contractor if the methods of arriving at these results are also specified. (*See J. C. Wait, Eng. News, June 8, 1905*). In either case considerable study should be given to securing a happy medium between brevity and elaboration of details. The degree of detail should be governed very largely by the magnitude and importance of the work.

The following is suggested as a suitable plan to follow in drawing up specifications for materials. It is the result of a study of this subject by a special committee of the American Society for Testing Materials.

Whatever form is adopted should be closely adhered to in writing all the specifications for a given job.

1. The specification shall be divided into eight "Parts."

2. The titles of these Parts shall be in large upper-case type centered over the text and preceded by a Roman numeral.

3. The titles of these Parts shall be as follows unless conditions necessitate some variation. In case a Part is omitted, the Roman numerals shall be continued in an unbroken sequence.

I. Manufacture.
II. Chemical Properties and Tests.
III. Physical Properties and Tests: Mechanical, Electrical, Magnetic, Thermal, etc.
IV. Standard Sizes, Dimensions, Weights, Gauges, etc.
V. Workmanship and Finish.
VI. Packing, Marking and Shipping.
VII. Inspection and Rejection.
VIII. Definition of Terms. (If a specification contains numerous terms that admit of ambiguity, they shall be defined under this sub-title.)

4. Each "Part" of a specification shall be divided into "Clauses" or "Sections," which shall be numbered continuously throughout the specification in Arabic numerals. Every Section or Clause of printed specifications shall have a marginal heading in bold-face type, briefly indicative of its content. If specifications are on one side of the paper, the clause titles shall be in the left-hand margin; if printed on both sides, as in a book, the clause titles shall be in the outside margins.

5. Each Section or Clause may be subdivided into paragraphs distinguished by lower-case italics in parenthesis.

6. Directly after the title of the specification insert sections of an introductory, descriptive or general character. No sub-title shall precede this matter, which shall precede Part I.

7. Desired values, rather than permissible limits, shall be given, followed by a statement with respect to permissible variations.

8. In so far as practicable, specified values shall be expressed in tabular form.

9. The Style sheets of the A.I.E.E., A.S.T.M., etc., should be followed in all matters pertaining to typography, standard terms, abbreviations, spelling, etc.

The words "shall" and "will" are used in the following sense by the American Society for Testing Materials. Use "shall" wherever the specifications are to be made binding on parties of the first or second part. Use "will" wherever the specifications are intended to express a declaration of purpose not mandatory upon the parties of the first or second part. Many engineers use "shall" to express a command binding on the Contractor and "will" to express a declaration of purpose binding the Purchaser.

Specifications for machinery, apparatus or construction work may be written in similar form using different Part headings. In the case of apparatus and machinery, the following sequence of Parts has been found very practical by the author of this article.

The object of the specification and general conditions to be met having been stated, the following parts follow:

I. Summarized Description of principal Characteristics and Conditions of Service.
II. Style and Description of Apparatus; Details of Construction.
III. Dimensions, Weights, Drawings and Schedules.
IV. Work to be done by other Contractors.
V. Performance and Tests.
  (a) Performance which may be checked by mere observation.
  (b) Factory Tests.
  (c) Performance and Tests after Erection.
VI. Workmanship and Finish.
VII. Packings, Marking, Shipping and Delivery.
VIII. Inspection and Rejection.
IX. Guarantees.
X. Conditional Payments. (The details of conditional payments depending upon results of inspection and tests.)
XI. Definition of Terms. (If a specification contains numerous terms that admit of ambiguity, they shall be defined under this sub-title.)

It will be observed that the sequence of topics in the above schedule approximately follows the order of the life history of the machine. The form may be extended upon this principle to cover any kind of work.

POINTS TO BE COVERED IN SPECIFICATIONS. — A specification should often cover the following points.

Items 1 to 3 refer to preliminary specifications only. Items 4 and 5 are frequently included in the contract proper.

1. These specifications are intended to furnish such information to the Bidders as will enable them to prepare detail plans upon which to give prices. Should any Bidder consider the requirements of these specifications prohibitive to the free exercise of his skill, any suggestions made by him will be duly considered.

2. Before a contract is awarded, final specifications will be prepared by the Company.

3. In comparing proposals due consideration will be given by the Company to availability, reliability, simplicity, cost of maintenance and quickness of delivery.

4. The Engineer agrees to consider all drawings submitted by Bidders as confidential, and that he will not show any such drawings to other manufacturers, whether they are tendering under this specification or not.

5. Definition of words describing the parties to the contract, such as "Contractor," "Purchaser," "Company," "Engineer."

6. Person or persons concerned and their respective powers.

7. Where work is to be done or material delivered.

8. The point where the work of two contracts meet should be carefully designated in both contracts, not merely in a general way, but specifically to the minutest detail.

9. The Contractor shall be responsible for the correctness of all drawings even after they are approved by the Engineer.

10. Materials ordered or work commenced prior to the approval of the drawings will be at the Contractor's risk.

11. No approved drawing may be changed without the approval of the Engineer.

12. The Contractor shall inspect the work of other contractors whose work affects his and shall notify the Engineer of anything which injuriously affects

his work. The Contractor shall give these other contractors the privilege of inspecting his work in so far as it affects the acceptance of their work.

13. Contractor shall not drill or in any way impair the strength of buildings or structures except with the written consent of the Engineer.

14. All work shall conform to the requirements of the "National Board of Fire Underwriters," and to all Government regulations.

15. The Contractor shall obtain all necessary permits from the City or County.

16. All like parts shall be interchangeable as far as practicable.

17. The Contractor shall install and maintain in his offices and at the site of the work such telephones as may be required by the Engineer, and shall place them at the disposal of the Engineer or his representative for any purpose relating to the execution of the contract.

18. The Standardization Rules of the A.I.E.E. and other similar documents should be followed wherever possible.

19. The provisions of the preliminary specification and those subsequently agreed upon between Company and Bidder should be incorporated as part of the final or contract specification.

POINTS TO BE COVERED IN CONTRACT. — In addition to items 5 and 6 above, the Engineer should make sure that the following points are included in the contract. The actual preparation of the contract, at least where the amount of money involved is large, should be left to a competent lawyer.

1. Description and value of bond and indemnity to be delivered by Contractor to Company.
2. Statement of fire insurance to be secured by Contractor for Company.
3. Protection of Company by Contractor against losses resulting from letters patent.
4. The work to be performed in such a way as not to interfere with safety and continuity of service.
5. Responsibility for damage to work from fire, floods, storm, earthquake, or any other cause whatsoever.
6. Contiguous work by other contractors shall not be delayed.
7. Statement of liquidated damages to be paid in the event of work not being completed on the date agreed.
8. The Contractor shall not transfer the contract without permission.
9. Time of commencement of work, rate of progress and date of completion.
10. The character of the methods and appliances to be used and grade of workmen to be employed.
11. Method of payment, time of settlement and basis thereof.
12. Arbitration and settlement of disputes.
13. Extras and claims therefor.

(The subject of Engineering contracts is more fully covered in the books by J. B. Johnson and J. I. Tucker, cited in the Bibliography.)

SPECIFICATIONS FOR MACHINES. — The following clauses are often useful in specifications for machinery. As presented here, they are necessarily somewhat special, and should not be adopted without modification unless after due consideration they are found applicable:

1. The Contractor shall furnish the services of experienced erecting engineers, who shall be constantly in charge of the work at the sites of erection, together with all necessary machinists, electricians, riggers and laborers to properly and quickly unload, erect, adjust, operate and test the machine.
2. The Company will supply crane service at a stated price per hour.
3. The Contractor will be held responsible for all operations connected with the handling of the machine on the premises of the Purchaser, and the Con-

tractor is to defray, make good or repair any loss, damage or cost occasioned by, or in consequence of, the careless or negligent handling of such machine or its parts.

4. Another Contractor will construct suitable foundations in accordance with detail plans to be prepared by the Engineer; data and dimensions required to prepare said plans to be furnished by the Contractor. The foundations will be constructed to the entire satisfaction of the Contractor, so far as they affect the final acceptance by the Engineer of the work furnished by said Contractor. The intention of this clause is to bar any claim by the Contractor that the foundations have not been constructed in such a manner as to enable him to fulfill all the provisions of the specification and the contract.

5. After the machine is erected and ready for regular service, the Contractor shall superintend the operation of it for a stated period. Attendance for this purpose will be furnished by the Company. The Contractor shall give full instructions regarding the adjustment, care, operation and maintenance of the machine to the representatives of the Company.

6. All castings shall be filled and carefully rubbed until practically smooth and of a uniform surface, then painted and rubbed and again painted before shipment. After erection all painted parts of the machine shall receive two finishing coats of hard drying paint of a color to be approved by the company, numbered as directed and finally given two coats of hard drying varnish. All finished steel or iron work shall be brightly polished and carefully slushed with white lead and tallow before shipment. After erection all finished work shall be cleaned and polished and the machine left in perfect condition.

7. The Contractor shall furnish a complete set of case-hardened wrenches mounted on a polished oak board, and all special tools or implements necessary for adjusting and handling the machine. He shall also furnish all oil and grease cups, oil gauges or other devices required to complete the oiling system.

Specifications for dynamo-electric machinery may also advantageously contain clauses on the following subjects:

8. Maximum permissible dimensions.
9. Leveling of foundations.
10. Who supplies and erects field-resistance boxes, dial plates, chains and panels.
11. Maximum reduction of commutator depth permissible by turning.
12. Amount of brush adjustment to allow for brush wear when commutator has been turned down to minimum size.
13. Staggering of brushes to prevent ridges on commutator.
14. Where terminal boards are to be located.
15. Tinning of connections.
16. Smoothness of armature slots.
17. Rigidity of overhanging armature windings.
18. Strength of armature-binding wire.
19. Means for turning over rotating part for inspection and repair.

STANDARDIZATION RULES OF THE A.I.E.E. — (*See also Standardization Rules and Standard Specifications.*) The first set of Standardization Rules issued by the American Institute of Electrical Engineers was the "Report of the Committee on Standardization" presented and accepted by the Institute June 26, 1899, and published in the *Trans. A.I.E.E.*, Vol. 16, p. 255. A revision of these rules was presented and adopted June 20, 1902, and these revised rules were published in the *Trans. A.I.E.E.*, Vol. 19, p. 1075. These rules were again revised and adopted by the Institute June 21, 1907, and appear in the *Trans. A.I.E.E.*, Vol. 26, p. 1795. Another revision of the Standardization Rules was approved by the Board of Directors on June 27, 1911, and appears in the *Trans. A.I.E.E.*, Vol. 30, p. 2535.

Since 1911 the Standards Committee of the Institute has been working on a complete revision of the rules, particularly with reference to methods of rating of electrical machinery. At a special meeting of the Board of Directors of the Institute held July 10, 1914, at which a draft of these new rules was presented, the following resolution was passed:

RESOLVED, that the rules reported by the Standards Committee be and hereby are adopted subject to editorial revision by the committee for the purpose of correcting errors and clarifying the real intent of the rules, the same to take effect December 1, 1914.

Below is reprinted the draft of the new Standardization Rules as presented at this meeting of the Board of Directors. The resolution passed by the Board would indicate that the rules which are to go into effect on December 1, 1914, will not differ materially from the draft given below.

Copies of the 1911 Edition of the Rules may be obtained from the Headquarters of the Institute, 33 W. 39th St., New York City, for 10 cents per copy in paper covers or for 25 cents per copy in cloth covers. The new rules will also undoubtedly be on sale in pamphlet form.

TABLE OF CONTENTS

DEFINITIONS

NOTE. — The following definitions are intended to be practically descriptive, and not scientifically rigid. The definitions of currents given below apply also, in most cases, to electromotive force, potential difference, magnetic flux, etc.

1. **A Direct Current** is a unidirectional current. As ordinarily used, the term designates a practically non-pulsating current.

2. **A Pulsating Current** is a current which pulsates regularly in magnitude. As ordinarily employed, the term refers to unidirectional current.

3. **A Continuous Current** is a practically non-pulsating direct current.

4. **An Alternating Current** is a current which alternates regularly in direction. Unless distinctly otherwise specified, the term "alternating current" refers to a periodic current with successive half waves of the same shape and area.

5. **An Oscillating Current** is a periodic current whose frequency is determined by the constants of the circuit or circuits.

6. **Cycle.** — One complete set of positive and negative values of an alternating current.

7. **Electrical Degree.** — The 360th part of a cycle.

8. **Period.** — The time required for the current to pass through one cycle.

9. **Frequency.** — The number of cycles or periods per second. The product of 2π by the frequency is called the *angular velocity* of the current.

10. **Root-Mean-Square or Effective Value.** — The square root of the mean of the squares of the instantaneous values for one complete cycle. It is usually abbreviated r.m.s. Unless otherwise specified, the numerical value of an alternating current refers to its r.m.s. value. The r.m.s. value of a sinusoidal wave is equal to its maximum value divided by $\sqrt{2}$. The word "virtual" is sometimes used in place of r.m.s., particularly in Great Britain.

11. **Wave-Form or Wave-Shape.** — The shape of the curve obtained when the instantaneous values of an alternating current are plotted against time in rectangular coördinates. The distance along the time axis corresponding to one complete cycle of values is taken as 2π radians, or 360°. Two alternating quantities are said to have the same wave-form when their ordinates of corresponding phase (see §13) bear a constant ratio to each other. The wave-shape, as thus understood, is therefore independent of the frequency of the current and of the scale to which the curve is represented.

12. **Simple Alternating or Sinusoidal Current.** — One whose wave-shape is sinusoidal.

Alternating-current calculations are commonly based upon the assumption of sinusoidal currents and voltages.

13. **Phase.** — The distance, usually in angular measure, of the base of any ordinate of an alternating wave from any chosen point on the time axis, is called the phase of this ordinate with respect to this point. In the case of a sinusoidal alternating quantity, the phase at any instant may be represented by the corresponding position of a line or *vector* revolving about a point with such an angular velocity ($\omega = 2\pi f$) that its projection at each instant upon a convenient reference line is proportional to the value of the quantity at that instant.

14. **Non-Sinusoidal Quantities** are quantities that cannot be represented by vectors of constant length in a plane, and the following definitions of phase, active component, reactive component, etc., are not in general applicable. Certain "equivalent" values, as defined below, may, however, be used in many instances, for the purpose of approximate representation and calculation.

15. **Crest-Factor or Peak-Factor** is the ratio of the crest or maximum value to the r.m.s. value. The crest factor of a sine-wave is $\sqrt{2}$.

16. **Form Factor** is the ratio of the r.m.s. to the algebraic mean ordinate taken over a half-cycle beginning with the zero value. If the wave passes through zero more than twice during a single cycle, that zero shall be taken which gives the largest algebraic mean for the succeeding half-cycle. The form factor of a sine-wave is 1.11.

17. **Distortion-Factor** of a wave is the ratio of the r.m.s. value of the first derivative of the wave with respect to time, to the r.m.s. value of the first derivative of the equivalent sine wave.

18. **Equivalent Sine Wave.** — A sine wave which has the same frequency and same r.m.s. value as the actual wave.

*19. **Phase Difference: Lead and Lag.**—When corresponding cyclic values of two sinusoidal alternating quantities of the same frequency occur at different instants, the two quantities are said to differ in phase by the angle between their nearest corresponding values, e.g., the phase angle between their nearest ascending zeros or positive maxima. That quantity whose maximum value occurs first in time is said to lead the other, and the latter is said to lag behind the former.

*20. **Counter-Clockwise Convention.**—It is recommended that in any vector diagram, the leading vector be drawn counter-clockwise with respect to the lagging vector,† as in the accompanying diagram, where *OI* represents the vector of a current in a simple alternating-current circuit lagging behind the vector *OE* of impressed e.mf.

*21. **The Active or In-Phase Component** of the current in a circuit is that component which is in phase with the voltage across the circuit; similarly the active component of the voltage across a circuit is that component which is in phase with the current. The use of the term *energy component* for this quantity is disapproved.

*22. **The Reactive or Quadrature Component** of the current in a circuit is that component which is in quadrature with the voltage across the circuit; similarly the reactive component of the voltage across the circuit is that component which is in quadrature with the current. The use of the term *wattless component* for this quantity is disapproved.

*23. **Reactive Factor** is the sine of the angular phase difference between voltage and current, or the ratio of the reactive current or voltage to the total current or voltage.

*24. **Reactive Volt-Amperes.** — The product of the reactive component of the voltage by the total current, or of the reactive component of the current by the total voltage.

*25. **Non-Inductive Load and Inductive Load.** — A *non-inductive* load is a load in which the current is in phase with the voltage across the load. An *inductive* load is a load in which the current lags behind the voltage across the load. A *condensive* or *anti-inductive* load is one in which the current leads the voltage across the load.

26. **Power in an Alternating-Current Circuit** is the average value of the products of the coincident instantaneous values of the current and voltage for a complete cycle, as determined by a wattmeter.

* Note. — Definitions 19, 20, 21, 22, 23, 24, 25 refer strictly only to cases where the voltage and current are both sinusoidal (see §12).

† See Publication 12 of the International Electrotechnical Commission (Report of Turin Meeting, Sept. 1911, p. 78).

27. **Volt-Amperes or Apparent Power.** — The product of the r.m.s. value of the voltage across a circuit by the r.m.s. value of the current in the circuit. This is ordinarily expressed in kv-a.

28. **Power Factor** is the ratio of the power (cyclic average as defined in §26) to the volt-amperes. In the case of sinusoidal current and voltage, the power factor is equal to the cosine of their difference in phase.

29. **Equivalent Phase Difference.** — When the current and e.m.f. in a given circuit are non-sinusoidal, it is customary, for purposes of calculation, to take as the "equivalent" phase difference the angle whose cosine is the power factor (see §28) of the circuit. There are cases, however, where this equivalent phase difference is misleading, since the presence of harmonics in the voltage wave, current wave, or in both, may reduce the power factor without producing a corresponding displacement of the two wave forms with respect to each other; e.g., the case of an a-c. arc. In such cases the components of the equivalent sine waves, the equivalent reactive factor and the equivalent reactive volt-amperes may have no physical significance.

30. **Single-Phase.** — A term characterizing a circuit energized by a single alternating e.m.f. Such a circuit is usually supplied through two wires. The currents in these two wires, counted positively outwards from the source, differ in phase by 180° or a half-cycle.

31. **Three-Phase.** — A term characterizing the combination of three circuits energized by alternating e.m.f.'s which differ in phase by one-third of a cycle; i.e., 120°.

32. **Quarter-Phase, also called Two-Phase.** — A term characterizing the combination of two circuits energized by alternating e.m.f.'s which differ in phase by a quarter of a cycle; i.e., 90°.

33. **Six-Phase.** — A term characterizing the combination of six circuits energized by alternating e.m.f.'s which differ in phase by one-sixth of a cycle; i.e., 60°.

34. **Polyphase** is the general term applied to any system of more than a single phase. This term is ordinarily applied to symmetrical systems.

35. **Per Cent Drop.** — In electrical machinery the ratio of the internal resistance drop to the terminal voltage is called the "*per cent resistance drop.*"

36. Similarly the ratio of the internal reactance drop to the terminal voltage is called the "*per cent reactance drop.*"

37. Similarly the ratio of the internal impedance drop to the terminal voltage is called the "*per cent impedance drop.*"

Unless otherwise specified, these per cent drops shall be referred to rated load and rated power factor.

38. In the case of transformers, the per cent drop will be the primary drop (reduced to secondary turns) plus the secondary drop, in per cent of secondary terminal voltage.

39. In the case of induction motors, it is advantageous to express the drops in per cent of the internally-induced e.m.f.

40. **The Load Factor** of a machine, plant or system is the ratio of the average power to the maximum power during a certain period of time. The average power is taken over a certain period of time, such as a day, a month, or a year, and the maximum is taken over a short interval of the maximum load within that period.

In each case, the interval of maximum load and the period over which the average is taken should be definitely specified, such as a "half-hour monthly"

load factor. The proper interval and period are usually dependent upon local conditions and upon the purpose for which the load factor is to be used.

41. **Plant Factor** is the ratio of the average load to the rated capacity of the power plant.

42. **The Demand** of an installation or system is the load which it puts on the source of supply, as measured at the receiving terminals. The demand may be as specified, contracted for, or used. It may be expressed either in kilowatts, kilovolt-amperes, amperes or other suitable units.

43. **Maximum Demand** of an installation or system is its greatest demand, as measured not instantaneously but over a suitable and specified interval, such as a "five-minute maximum demand."

44. **Demand Factor** is the ratio of the maximum demand of any system or part of a system to the total connected load of the system, or of the part of the system, under consideration.

45. **Diversity Factor** is the ratio of the sum of the maximum power demands of the subdivisions of any system or parts of a system to the maximum demand of the whole system or of the part of the system under consideration, measured at the point of supply.

46. **Connected Load.** — The combined continuous rating of all the receiving apparatus on consumers' premises connected to the system or part of the system under consideration.

47. **The Saturation Factor** of a machine is the ratio of a small percentage increase in field excitation to the corresponding percentage increase in voltage thereby produced. Unless otherwise specified, the saturation factor of a machine refers to the excitation existing at normal rated speed and voltage. It is determined from measurements of saturation made on open circuit at rated speed.

48. **The Percentage of Saturation** of a machine at any excitation may be found from its saturation curve of generated voltage as ordinates, against excitation as abscissas, by drawing a tangent to the curve at the ordinate corresponding to the assigned excitation, and extending the tangent to intercept the axis of ordinates drawn through the origin. The ratio of the intercept on this axis to the ordinate at the assigned excitation, when expressed in percentage, is the percentage of saturation and is independent of the scales selected for excitation and voltage. This ratio, as a fraction, is equal to the reciprocal of the saturation-factor at the same excitation, deducted from unity, or if f be the saturation factor and p the percentage of saturation.

$$p = 100\left(1 - \frac{1}{f}\right)$$

49. **Magnetic Degree.** —The 360th part of the angle subtended, at the axis of a machine, by a pair of its field poles. One mechanical degree is thus equal to as many magnetic degrees as there are pairs of poles in the machine.

50. **The Variation in Prime Movers** which do not give an absolutely uniform rate of rotation or speed, as in reciprocating steam engines, is the maximum angular displacement in position of the revolving member expressed in degrees, from the position it would occupy with uniform rotation, and with one revolution taken as 360°.

51. **The Variation in Alternators** or alternating-current circuits in general, is the maximum angular displacement, expressed in electrical degrees (one cycle = 360°), of corresponding ordinates of the voltage wave and of a wave of absolutely constant frequency equal to the average frequency of the alternator or circuit in question, and may be due to the variation of the prime mover.

52. **Relations of Variations in Prime Mover and Alternator.**—If p is the number of pairs of poles, the variation of an alternator is p times the variation of its prime mover, if direct-connected, and pn times the variation of the prime mover if rigidly connected thereto in such a manner that the angular speed of the alternator is n times that of the prime mover.

53. **The Pulsation in Prime Movers,** or in the alternator connected thereto, is the ratio of the difference between the maximum and minimum velocities in an engine-cycle to the average velocity.

54. **Capacity.** — The two different senses in which this word is used sometimes lead to ambiguity. It is therefore recommended that whenever such ambiguity is likely to arise, the descriptive term *power capacity* or *current capacity* be used, when referring to the power or current which a device can safely carry, and that the term "*Capacitance*" be used when referring to the electrostatic capacity of a device.

55. **A Resistor** is a device, commonly known as a resistance, used for the operation, protection or control of a circuit or circuits.

56. **A Reactor** is a coil, winding or conductor commonly known as a reactance coil or choke coil, possessing inductance, the reactance of which is used for the operation, protection or control of a circuit or circuits.

57. **The Efficiency** of an electrical machine or apparatus is the ratio of its useful output to its total input.

SYMBOLS AND ABBREVIATIONS

58. *The list recommended is given in the article on Abbreviations and Symbols, p. 1.*

59. E_m, I_m and P_m should be used for maximum cyclic values, e, i and p for instantaneous values, E and I for r.m.s. values (see §10) and P for the average value or active power. These distinctions are not necessary in dealing with continuous-current circuits. In print, vector quantities should be represented by bold-face capitals.

CLASSIFICATION OF MACHINERY

60. The machinery under consideration in these rules may be classified in various ways, these various classifications overlapping or interlocking in considerable degree. Briefly, they are Direct-Current or Alternating-Current, Rotating or Stationary. Under Rotating Apparatus there are two principal classifications: *First,* according to the function of the machines; Motors, Generators, Boosters, Motor-Generators, Dynamotors, Double-current Generators, Converters and Phase Modifiers; *Second,* according to the type of construction or principle of operation; Commutating, Synchronous, Induction, Unipolar, Rectifying. Obviously some of these groups could be rationally included in either classification, e.g., Motor-Generators and Rectifying Machines.

In the following, the self-evident definitions are for the most part omitted.

FUNCTIONAL CLASSIFICATION OF ROTATING MACHINES

61. **A Generator** is a machine which transforms mechanical power into electrical power.

62. **A Motor** transforms electrical power into mechanical power.

63. **A Booster** is a generator inserted in series in a circuit to change its voltage. It may be driven by an electric motor (in which case it is termed a motor-booster) or otherwise.

64. **A Motor Generator** is a transforming device consisting of a motor mechanically coupled to one or more generators.

65. **A Dynamotor** is a transforming device combining both motor and generator action in one magnetic field, either with two armatures, or with one armature having two separate windings and independent commutators.

66. **A Direct-current Compensator** or **Balancer** comprises two or more similar direct-current machines (usually with shunt or compound excitation) directly coupled to each other and connected in series across the outer conductors of a multiple-wire system of distribution, for the purpose of maintaining potentials of the intermediate wires of the system, which are connected to the junction points between the machines.

67. **A Double-current Generator** supplies both direct and alternating currents from the same armature-winding.

68. **A Converter** is a machine employing mechanical rotation in changing electrical energy from one form into another. A converter may belong to either of several types, as follows:

69. **A Direct-current Converter** converts from a direct current to a direct current, usually with a change of voltage. Such a machine may be either a motor generator or a dynamotor.

70. **A Synchronous Converter** (also called a Rotary Converter) converts from an alternating to a direct current, or vice-versa. It is a synchronous machine with a single closed-coil armature.

71. **A Cascade Converter,** also called a **Motor Converter,** is a combination of an induction motor with a synchronous converter, the secondary circuit of the former feeding directly into the armature of the latter; i.e., it is a synchronous converter concatenated with an induction motor.

72. **A Frequency Converter** converts the power of an alternating-current system from one frequency to another, with or without a change in the number of phases, or in the voltage.

73. **A Rotary Phase-Converter** converts from an alternating-current system of one or more phases to an alternating-current system of a different number of phases, but of the same frequency.

74. **A Phase-Modifier,** also called *a Phase-Advancer*, is a machine which supplies reactive volt-amperes to the machine; e.g., induction motor, or to the system to which it is connected. Phase modifiers may be either synchronous or asynchronous.

75. **A Synchronous Phase-Modifier,** sometimes called a Synchronous Condenser, is a synchronous motor, running either idle or with load, the field excitation of which may be varied so as to modify the power-factor of the system, or through such modification to influence the load voltage. The function of a Synchronous Phase-Modifier is to supply reactive volt-amperes to the system with which it is connected.

CONSTRUCTIONAL CLASSIFICATION OF ROTATING MACHINES

Commutating Machines:

76. **Direct-current Commutating Machines** comprise a magnetic field of constant polarity, an armature and a multi-segmental commutator connected therewith. These include: Direct-current Generators; Direct-current Motors; Direct-current Boosters; Direct-current Motor-Generators and Dynamotors; Direct-current Compensators or Balancers; and Arc Machines.

77. **Alternating-current Commutating Machines*** comprise a magnetic field of alternating polarity, an armature and multi-segmental commutator connected therewith.

78. **Synchronous Commutating Machines** include synchronous converters, cascade-converters and double-current generators.

79. **Synchronous Machines** comprise a constant magnetic field and an armature receiving or delivering alternating currents in synchronism with the motion of the machine; i.e., having a frequency strictly proportional to the speed of the machine. They may be subdivided as follows:

80. **An Alternator** is a synchronous alternating-current generator, either single phase or polyphase.

81. **A Polyphase Alternator** is a polyphase synchronous alternating-current generator.

82. **An Inductor Alternator is a Synchronous Alternator** in which both field and armature windings are stationary and in which masses of iron or inductors, by moving past the coils, alter the magnetic flux through them. It may be either single phase or polyphase.

83. **A Synchronous Motor** is a machine structurally identical with a synchronous alternator, but operated as a motor.

84. **Induction Machines** include apparatus wherein the primary and secondary windings rotate with respect to each other; i.e., induction motors, induction generators, certain types of frequency converters and certain types of rotary phase-converters.

85. **An Induction Motor** is an alternating-current motor, either single phase or polyphase, comprising independent primary and secondary windings, one of which, usually the secondary, is on the rotating member. The secondary winding receives power from the primary by electromagnetic induction.

86. **An Induction Generator** is a machine structurally identical with an induction motor, but driven above synchronous speed as an alternating-current generator.

87. **Unipolar or Acyclic Machines** are direct-current machines, in which the voltage generated in the active conductors maintains the same direction with respect to those conductors.

SPEED CLASSIFICATION OF MOTORS

88. Motors may, for convenience, be classified with reference to their speed characteristics as follows:

89. *a.* **Constant-speed Motors,** in which the speed is either constant or does not materially vary; such as synchronous motors, induction motors with small slip and ordinary direct-current shunt motors.

90. *b.* **Multi-speed Motors** (two-speed, three-speed, etc.), which can be operated at any one of several distinct speeds, these speeds being practically independent of the load, such as motors with two armature windings, or induction motors with controllers for changing the number of poles.

* Definitions of a-c. commutator-motors have not yet been agreed upon. The differences of opinion are fundamental and relate to the whole system to be employed in naming the numerous types. One example of this difference is in connection with the definition of the term "Repulsion-Motor," some desiring to extend its use to cover all a-c. commutator motors with short-circuited brushes, and others to substitute more systematic names for the various species of short-circuited brush motors.

91. *c.* **Adjustable-speed Motors,** in which the speed can be varied gradually over a considerable range, but when once adjusted remains practically unaffected by the load, such as shunt motors designed for a considerable range of field variation.

92. *d.* **Varying-speed Motors,** or motors in which the speed varies with the load, ordinarily decreasing when the load increases; such as series motors, compound-wound motors and series-shunt motors.

CLASSIFICATION OF ROTATING MACHINES RELATIVE TO THE DEGREE OF ENCLOSURE OR PROTECTION

93. The following types are recognized:

(1) Open	(7) Self-ventilated
(2) Protected	(8) Drip-proof
(3) Semi-enclosed	(9) Moisture resisting
(4) Enclosed	(10) Submersible
(5) Externally ventilated	(11) Flame-proof
(6) Water-cooled	(12) Flame-proof slip-ring enclosure

94. No. 1. **An "open" machine** is of either the pedestal-bearing or end-bracket type where there is no restriction to ventilation, other than that necessitated by good mechanical construction.

95. No. 2. **A "protected" machine** is one in which the armature, field coils and other live parts are protected mechanically from accidental or careless contact, while free ventilation is not materially obstructed.

96. No. 3. **A "semi-enclosed" machine** is one in which the ventilating openings in the frame are protected with wire screen, expanded metal, or other suitable perforated covers, having apertures not exceeding ¼ of a square inch (1.6 sq. cm.) in area.

97. No. 4. **An "enclosed" machine** is so completely enclosed by integral or auxiliary covers as to prevent a circulation of air between the inside and outside of its case, but not sufficiently tight to be termed air-tight.

98. No. 5. **An "externally ventilated" machine** has its ventilating air supplied by an independent fan or blower external to the machine.

99. No. 6. **A "water-cooled" machine** is one which mainly depends on water circulation for the removal of its heat.

100. No. 7. **A "self-ventilated" machine** differs from an externally ventilated machine only in having its ventilating air circulated by a fan, blower, or centrifugal device integral with the machine.

If the heated air expelled from the machine is conveyed away through a second pipe attached to the machine, this should be so stated.

101. No. 8. **A "drip-proof" machine** is one provided with ventilating openings, so protected as to exclude falling moisture or dirt.

102. No. 9. **A moisture-resisting machine** is one in which all parts are treated with moisture-resisting material. Such a machine shall be capable of operating continuously or intermittently in a very humid atmosphere, such as in mines, evaporating rooms, etc.

103. No. 10. **A "submersible" machine** is a waterproof machine capable of withstanding complete submersion for four hours without injury.

104. No. 11. **A "flame-proof" machine** is a machine in which the enclosing case can withstand, without injury, any explosion of gas that may occur within it, and will not transmit the flame to any inflammable gas outside it.

105. No. 12. **Flame-proof Slip-ring Enclosure.** — An induction motor in which the slip rings and brushes alone are included within a flame-proof case should not be described as a flame-proof machine, but as a machine "with flame-proof slip-ring enclosure."

STATIONARY INDUCTION APPARATUS

107.* **Stationary Induction Apparatus** changes electric energy to electric energy through the medium of magnetic energy without mechanical motion. It comprises several forms, distinguished as follows:

108. **Transformers,** in which the primary and secondary windings are ordinarily insulated one from another.

109. **High-voltage, Low-voltage, Primary, Secondary.** — The terms "high-voltage" and "low-voltage" are used to distinguish the winding having the greater from that having the lesser number of turns. The terms "primary" and "secondary" serve to distinguish the windings in regard to energy flow, the primary being that which receives the energy from the supply circuit, and the secondary that which receives the energy by induction from the primary.

110. **The Rated Current of a Constant-potential Transformer** is that secondary current which, multiplied by the rated-load secondary voltage, gives the kv-a. rated output. That is, a transformer of given kv-a. rating must be capable of delivering the rated output at rated secondary voltage, while the primary impressed voltage is increased to whatever value is necessary to give rated secondary voltage.

The rated primary voltage of a constant-potential transformer is the rated secondary voltage multiplied by the turn ratio.

111. **The Voltage Ratio** of a transformer is the ratio of the r.m.s. primary terminal voltage to the r.m.s. secondary terminal voltage under specified conditions of load.

112. **The Current Ratio** of a current-transformer is the ratio of r.m.s. primary current to r.m.s. secondary current under specified conditions of load.

113. **The Ratio of a Transformer,** unless otherwise specified, shall be the ratio of the number of turns in the high-voltage winding to that in the low-voltage winding; i.e., the "turn-ratio."

114. **The Marked Ratio** of an instrument transformer is the ratio which the apparatus is designed to possess under average conditions of use. When a precise ratio is required, it is necessary to specify the voltage, frequency, load and power factor of the load.

115. **Auto-transformers** have a part of their turns common to both primary and secondary circuits.

116. **Voltage Regulators** have turns in shunt and turns in series with the circuit, so arranged that the voltage ratio of the transformation or the phase relation between the circuit-voltages is variable at will. They are of the following three classes:

117. **Contact Voltage Regulators,** in which the number of turns in one or both of the coils is adjustable.

118. **Induction Voltage Regulators,** in which the relative positions of the primary and secondary coils are adjustable.

119. **Magneto Voltage Regulators,** in which the direction of the magnetic flux with respect to the coils is adjustable.

* There is no §106 in the original, [Editor].

120. **Reactors** or **Reactance-Coils,** also called **Choke Coils;** a form of stationary induction apparatus used to supply reactance or to produce phase displacement.

INSTRUMENTS

121. **An Ammeter** is a measuring instrument, indicating in amperes.

122. **A Voltmeter** is a measuring instrument, indicating in volts.

123. **A Wattmeter** is an instrument for measuring electrical power, indicating in watts.

124. **Recording Ammeters, Voltmeters, Wattmeters, etc.,** are instruments which record graphically upon a time-chart the values of the quantities they measure.

125. **A Watt-hour Meter** is an instrument for registering watt-hours. This term is to be preferred to the term "integrating wattmeter."

126. **A Line-drop Voltmeter Compensator** is a device in connection with a voltmeter, which causes the latter to indicate the voltage at some distant point of the circuit.

127. **A Synchroscope, sometimes called Synchronoscope,** is a device which, in addition to indicating synchronism, shows whether the machine to be synchronized is fast or slow.

STANDARDS FOR ELECTRICAL MACHINERY

128. **Notes.** — The expression "machinery" is here employed in a general sense in order to obviate the constant repetition of the words "machinery or induction apparatus."

129. All temperatures are to be understood as centigrade.

130. The expression "capacity" is to be understood as indicating "capability" except where specifically qualified, as, for instance, in the case of allusions to electrostatic capacity, i.e., capacitance.

131. Wherever special rules are given for any particular type of machinery or apparatus (such as railway motors, railway substation machinery, switches, etc.), these special rules shall be followed, notwithstanding any apparent conflict with the provisions of the more general sections. In the absence of special rules on any particular point, the general rules on this point shall be followed.

132. **Objects of Standardization.** — To ensure satisfactory results, electrical machinery should be specified to conform to the Institute Standardization Rules in order that it shall comply, in operation, with approved limitations in the following respects so far as they are applicable.

Operating temperature	Efficiency
Mechanical strength	Power factor
Commutation	Wave shape
Insulation strength	Regulation

133. **Capacity of an Electrical Machine.** — So far as relates to the purposes of these Standardization Rules, the Institute defines the Capacity of an Electrical Machine as the load or task of which it is capable for a specified time (or continuously), without exceeding in any respect the limitations herein set forth.

Except where otherwise specified, the capacity of an electrical machine shall be expressed in terms of its *output*. For exceptions see §140 and 418.

134. **Rating of an Electrical Machine.** — Capacity should be distinguished from Rating. The Rating of a machine is the output marked on the

Rating Plate, and shall be based on, but shall not exceed, the maximum* load which can be taken from the machine under prescribed conditions of test. This is also called the rated output.

135. **A.I.E.E. and I.E.C. Ratings.** — When the prescribed conditions of test are those of the A.I.E.E. Standardization Rules, the rating of the machine is the Institute Rating. When the prescribed conditions of the test are those of the I.E.C. Rules, the rating of the machine is the I.E.C. rating. A machine so rated in either case shall bear a distinctive sign upon its rating plate.

136. **Standard Temperature and Barometric Pressure for Institute Rating.** — The Institute Rating of a machine shall be its capacity when operating with a cooling medium of the ambient temperature of reference (40° for air or 25° for water, see §§153 and 157) and with barometric conditions within the range given in §156. See §168.

UNITS IN WHICH RATING SHALL BE EXPRESSED

137. **Direct-Current Generators.** — In the case of direct-current generators, the rating shall be expressed in kilowatts (kw.) available at the terminals.

138. **Alternators and Transformers.** — In the case of alternators and transformers, the rating shall be expressed in kilovolt-amperes (kv-a.) available at the terminals, at a specified power factor. The corresponding kilowatts shall also preferably be stated.

139. **Motors.** — In the case of motors, the rating shall be expressed in kilowatts† (kw.) available at the shaft. (An exception to this rule is made in the case of Railway motors, which for some purposes are also rated by their kilowatts *input*, see §418.)

140. **Auxiliary machinery,** such as regulators, phase controllers, resistors, reactors, balancer sets, stationary and synchronous condensers, etc., shall have their ratings expressed in terms of the functions which they perform. It is essential to specify also the voltage of the circuits on which the machinery may appropriately be used.

KINDS OF RATING

141. There are two kinds of rating: namely, (1) rating for continuous service, i.e., "continuous rating;" (2) rating for discontinuous service, i.e., "short-time rating."

142. **Continuous Rating.** — A machine rated for continuous service shall be able to operate continuously at its rated output, without exceeding any of the limitations referred to in §132.

* The term "maximum load" does not refer to loads applied solely for mechanical, commutation, or similar tests.

† Since the input of machinery of this class is measured in electrical units and since the output has a definite relation to the input, it is logical and desirable to measure the delivered power in the same units as are employed for the received power. Therefore, the output of motors should be expressed in kilowatts instead of in horse power. However, on account of the hitherto prevailing practice of expressing mechanical output in horse power, it is recommended that for machinery of this class the rating shall, for the present, be expressed both in kilowatts and in horse power, as follows:

kw.———— h.p.————

The horse-power rating of a motor may, for practical purposes, be taken as 4/3 of the kilowatt rating.

In order to lay stress upon the preferred future basis, it is desirable that on Rating Plates, the Rating in kilowatts shall be shown in larger and more prominent characters than the rating in horse power.

143. Short-time Rating. — A machine rated for short-time service (i.e. service including runs alternating with stoppage of sufficient duration to ensure substantial cooling) shall be able to operate at its rated output during a limited period, to be specified in each case, without exceeding any of the limitations referred to in §132. Such a rating is a short-time rating.

144. Nominal Ratings. — For railway motors and railway substation machinery, certain nominal ratings are employed. See §§391 and 415.

145. Duty-cycle Operation. — Many machines are operated on a cycle of duty which repeats itself with more or less regularity. For purposes of rating, either a continuous or a short time "equivalent load" may be selected which shall simulate as nearly as possible the thermal conditions of the actual duty cycle.

146. Standard Durations of Equivalent Tests shall be for machines operating under specified duty-cycles:

5 minutes	60 minutes
10 minutes	120 minutes
30 minutes	and continuous

Of these the first five are short-time ratings selected as being thermally equivalent to the specified duty cycle.

When, for example, a short time rating of 10 minutes' duration, is adopted, and the thermally equivalent load is 25 kw. for that period, then such a machine shall be stated to have a 10-minute rating of 25 kw.

147. In every case the equivalent short-time test shall commence only when the windings and other parts of the machine are *within 5° C. of the ambient temperature* at the time of starting the test.

148. In the absence of any specification as to the kind of rating, the continuous rating shall be understood.*

Machines marked in accordance with §135 shall be understood to have a continuous rating unless otherwise marked in accordance with §146.

HEATING AND TEMPERATURE

149. Temperature Limitations of the Capacity of Electrical Machinery. — The capacity, so far as relates to temperature, is usually limited by the maximum temperature at which the materials in the machine, especially those employed for insulation, may be operated for long periods without deterioration. When the safe limits are exceeded, deterioration is rapid. The insulating material becomes permanently damaged by excessive temperature, the damage increasing with the length of time that the excessive temperature is maintained, and with the amount of excess temperature, until finally the insulation breaks down.

150. The result of operating at temperatures in excess of the safe limit is to shorten the life of the insulating material. This shortening of life is, in certain special cases, warranted, when necessary for obtaining some other desirable result, as, for example, in some instances of railway motors, in providing greater power within a limited space. See §419. Exceptions may also be noted in the cases of contactors, arc-lamp magnet windings, etc., designed and constructed for operation at relatively-high temperatures.

* An exception is made in the case of machines for railway service, where in the absence of any specification as to the kind of rating, the "nominal rating" as defined in §§391 and 415 shall be understood.

151. There does not appear to be any advantage in operating at lower temperatures than the safe limits, so far as the life of the insulation is concerned. Insulation may break down from various causes, and generally, when these breakdowns occur, it is not due to the temperature at which the insulation has been operated, provided the safe limits have not been exceeded.

152. **The Ambient Temperature** is the temperature of the fluid or fluids which, coming into contact with the heated parts of a machine, carries off its heat convectively.

The cooling fluid may either be led to the machine through ducts, or merely surround the machine freely. In the former case the ambient temperature is to be measured at the intake of the machine. In the latter case see §163.

153. **Ambient Temperature of Reference for Air.** — The standard ambient temperature of reference, when the cooling medium is air, shall be 40° C.

154. The permissible rises in temperature given in column 2 of the table in §188 have been calculated on the basis of the standard ambient temperature of reference, by subtracting 40° from the highest temperatures permissible, which are given in column 1 of the same table.

155. A machine may be tested at any convenient ambient temperature, but whatever be the value of this ambient temperature, the permissible rises of temperature must not exceed those given in column 2 of the table in §188.

156. **Altitude.** — Increased altitude has the effect of increasing the temperature rise of some types of machinery. In the absence of information in regard to the height above sea level at which the machine is intended to work in ordinary service, this height is assumed not to exceed 1000 meters (3300 feet). For machinery operating at an altitude of 1000 meters or less, a test at any altitude less than 1000 meters is satisfactory, and no correction shall be applied to the observed temperatures. Machines intended for operation at higher altitudes shall be regarded as special. When a machine is rated for service at altitudes above 1000 meters (3300 ft.) the normal permissible temperature rise, until more nearly accurate information is available, shall be reduced by 1 per cent for each 100 meters (330 ft.) by which the altitude exceeds 1000 meters. Water-cooled oil transformers are exempt from this reduction.

157. **Ambient Temperature of Reference for Water-cooled Machinery.** — For water-cooled machinery the standard temperature of reference for incoming cooling water shall be 25° C., measured at the intake of the machine.

158. **In Testing Water-cooled Transformers,** it is important, especially for the smaller sizes, to maintain the temperature of the ingoing water within 5° C. of the surrounding air. Where this is impracticable, the reference ambient temperature shall be taken as that indicated by the resistance of the windings, when the disconnected transformer is being supplied with the normal amount of cooling water and the temperature of the windings has become constant.

159. **Machinery Cooled by Air Led to the Machine from a Distance through Ventilating Ducts.** — In this case the temperature of the ingoing air shall be measured at the intake of the machine. The ambient temperature shall be determined in the manner specified in §158 for water-cooled transformers.

160. **Rotating Machines.** — In the case of rotating machines, the above method becomes inapplicable, and recourse must be had to a weighted mean between the temperatures of the circulating air and of the surrounding air. If the necessary thermal data are known, this weighted mean can be calculated; but it shall be permitted to employ a conventional weighted mean, by giving a weight of four to the circulating air and of one to the surrounding room air, provided that these two temperatures during the test do not differ by more than 10 °C.

161. **Machines Cooled by Other Means.** — For machines cooled by other means, special rules are necessary.

162. **Outdoor Machinery Exposed to Sun's Rays.** — Outdoor machinery not protected from the sun's rays at times of heavy load must receive special consideration as regards ambient temperature.

163. **Measurement of the Ambient Temperature During Tests of Machinery.** — The ambient temperature is to be measured by means of several thermometers placed at different points around and half way up the machine at a distance of 1 to 2 meters (3 to 6 feet), and protected from drafts, and abnormal heat radiation, preferably as in §165.

164. The value to be adopted for the ambient temperature during a test is the mean of the readings of the thermometers (placed as above) taken at equal intervals of time during the last quarter of the duration of the test.

165. **Errors due to the Time Lag.** — In order to avoid errors due to the time lag between the temperature of large machines and the variations in the ambient air, all reasonable precautions must be taken to reduce these variations and the errors arising therefrom. Thus, the thermometer for determining the ambient temperature shall be immersed in a suitable liquid, such as oil, in a suitable heavy metal cup. This can be made to respond to various rates of change, by proportioning the amount of oil to the metal in the containing cup. A convenient form for such an oil-cup consists of a massive metal cylinder with a hole drilled partly through it. This hole is filled with oil and the thermometer is placed therein with its bulb well immersed. The larger the machine under test, the larger should be the metal cylinder employed as an oil-cup in the determination of the ambient temperature. The smallest size of oil cup employed in any case shall consist of a metal cylinder 25 mm. in diameter and 50 mm. high (1 in. in diameter and not less than 2 in. high).

166. **In Testing Transformers** and sometimes other machines it will often be desirable to avoid errors due to time lag in temperature changes by employing an idle unit of the same size and subjected to the same conditions of cooling as the unit under test, for obtaining the ambient temperature as described in § 158 and §159.

167. **Where Machines are Partly Below the Floor Line** in pits, the temperature of the rotor shall be referred to a weighted mean of the pit and room temperatures, the weight of each being based on the relative proportions of the machine in and above the pit. Parts of the stator constantly in the pit shall be referred to the ambient temperature in the pit.

168. **Corrections for the Deviation of the Ambient Temperature, at the Time of Test, from the Reference Value of 40° C.** In view of numerous experiments which have shown that the effect on the temperature rise of the precise value of the ambient temperature at the time of test, is small, obscure and of doubtful direction, no correction shall be made for ambient temperature deviations from the standard value of 40° C. It is, however, desirable that tests should be conducted at ambient temperatures not lower than 25° C. Exception to this rule is made in the case of air-blast transformers, in which, if the ingoing air temperature during the test differs from 40° C., correction on account of difference in resistance and difference in convection shall be made by changing the "observable" temperature rise of the windings by 0.5 per cent for each degree centigrade. Thus with a room temperature of 30° C. the "observable" rise of temperature shall be increased by 5 per cent, and with a room temperature of 15° C. the "observable" rise of temperature shall be increased by 12.5 per cent.

169. Duration of Heat Run. — For practical purposes the duration of a test of a machine for continuous service shall be prolonged until the difference between the temperature of the machine and the ambient temperature is practically constant. Temperature measurements, when possible, shall be taken during operation, as well as when the machine is stopped. The highest figures thus obtained shall be adopted. In order to abridge the long heating period, in the case of large machines, reasonable overloads of current during the preliminary period are suggested for them.

OPERATING TEMPERATURES

170. The actual temperatures attained in the different parts of a machine, and not the rises in temperature, affect the life of the insulation of the machine. (See §§149 to 151.)

171. The temperatures in the different parts of a machine which it is desired to ascertain are the maximum temperatures reached in those parts.

172. As it is usually impossible to determine the maximum temperature attained in insulated windings, it is convenient to apply a correction to the measured temperature, to approximate the difference between the actual maximum temperature and the measured temperature by the method used. This correction or margin of security is provided to cover the errors due to fallibility in the location of the measuring devices, as well as inherent inaccuracies in measurement and methods.

TEMPERATURE MEASUREMENTS

173. In determining the temperature of different parts of a machine, three methods will be considered. One or other of these methods, as set forth below, will usually be appropriate for commercial measurements on any particular type of machine.

174. **Method No. 1. Thermometer Method.** — This method consists in the determination of the temperature by mercury or alcohol thermometers, by resistance thermometers, or by thermocouples, any of these instruments being applied to the hottest accessible part of the *completed* machine, as distinguished from the thermocouples or resistance coils imbedded in the machine, as described under Method No. 3.

175. When Method No. 1 is used, the hottest-spot temperature shall be estimated by adding a hottest-spot correction of 15° C. to the highest temperature observed.

176. *Exception.* — In cases where the thermometer is applied directly to the surface of a bare winding, such as an edgewise strip conductor, or a copper casting, a hottest-spot correction of 5° C. instead of 15° C. shall be made, in order to allow for the unlikelihood of locating the thermometer at the hottest spot.

177. **Method No. 2. Resistance Method.** — This method consists in the measurement of the temperature of windings by their increase in resistance, corrected* to the instant of shut-down when necessary. In the application of

* Whenever a sufficient time has elapsed between the instant of shut-down and the time of the final temperature measurement to permit the temperature to fall, suitable corrections shall be applied so as to obtain as nearly as practicable the temperature at the instant of shut-down. This can sometimes be approximately effected by plotting a curve, with temperature readings as ordinates and time as abscissas, and extrapolating back to the instant of shut-down. In other instances, acceptable correction factors can be applied.

In cases where successive measurements show *increasing* temperatures after shut-down, the highest value shall be taken.

this method careful thermometer measurements must also be made whenever practicable without disassembling the machine,* in order to increase the probability of revealing the highest observable temperature. Whichever method yields the higher temperature, that temperature shall be taken as the "highest observable" temperature and a hottest-spot correction of 10° C. added thereto.

178. In the case of resistance measurements, the temperature coefficient of copper shall be deduced from the formula $1/(234.5 + t)$. Thus, at an initial temperature $t = 40°$ C. the temperature coefficient or increase in resistance per degree centigrade rise is $1/(274.5) = 0.00364$. The following table, deduced from the formula, is given for convenience of reference.

Temperature of the winding, in degrees C. at which the initial resistance is measured	Increase in resistance of copper per ohm per degree C.
0	0.00427
5	0.00418
10	0.00409
15	0.00401
20	0.00393
25	0.00385
30	0.00378
35	0.00371
40	0.00364

179. In Field Coils of Low Resistance, where the joints and connections form a considerable part of the total resistance, the measurement of temperature by the resistance method shall not be used.

180. The Temperature of the Windings of Transformers is always to be ascertained by Method 2. In the case of air-blast transformers, it is especially important to place thermometers near the air outlet.

182.† Method No. 3. Imbedded Temperature-detector Method.—Thermocouples or resistance coils, located as nearly as possible at the estimated hottest spot. This method is only to be used with coils placed in slots.

183. By Building into the Machine suitably placed thermocouples or resistance coils, a temperature not much less than that of the hottest spot will be disclosed. When these devices are adopted for such temperature determinations, a liberal number shall be employed, and all reasonable efforts consistent with safety shall be made to locate them at the various places where the highest temperatures are likely to occur.

184. Temperature-Detectors should be placed in at least two sets of locations. One of these should be between coil and core, and one between the top and bottom coils, where two coils per slot are used. Where only one coil per slot is used, one set of detectors shall be placed between coil and core, and one set between coil and wedge.

185. Method No. 3 should be applied to all stators of machines with wide cores (50 cm. — 20 in. — and over) and to all machines of 5000 volts and over, if of over 500 kv-a., regardless of core width.

* As one of the few instances in which the thermometer check cannot be applied in Method No. 2, the rotor of a turbo-alternator may be cited.

† There is no § 181 in the original. [Editor].

186. Correction Factor for this Method.—On two-layer machines with couples between coils, and between coil and slot, add 5° to the highest reading. In single-layer machines with couples between coil and core and between coil and wedge, add to the highest reading 10° C. plus 1° C. per 1000 volts above 5000 volts of terminal pressure.

TEMPERATURE LIMITS

187. The following table gives the limits for the hottest-spot temperatures of insulations. The permissible limits are indicated in column 1 of the table. The limits of temperature rise permitted under rated-load conditions are given in column 2, and are found by subtracting 40° C. from the figures in column 1. Whatever be the ambient temperature at the time of the test, the rise of temperature observed must never exceed the limits in column 2 of the table. The highest temperatures attained in any machine corresponding to the output for which it is rated must not exceed the values indicated in column 1 of the table and clauses following.

188. Table of Hottest-spot Temperatures and of Corresponding Permissible Temperature Rises.

Class	Description of insulation	Column 1 Highest permissible temperatures for hottest spot	Column 2 Highest permissible temperature rise of hottest spot above 40° for the purpose of fixing the Institute rating
		° C.	° C.
A1	Cotton, silk, paper and other fibrous materials, not so treated as to increase the thermal limit.	95	55
A2	Similar to A1, but treated or impregnated and including enameled wire.	105	65
B	Mica, asbestos or other material capable of resisting high temperatures, in which any Class A material or binder, if used, is for structural purposes only, and may be destroyed without impairing the insulating or mechanical qualities.	125	85

189. **Note.**—The Institute recognizes the ability of manufacturers to employ Class B insulation successfully at maximum temperatures of 150° C. and even higher. However, as sufficient data covering experience over a period of years at such temperatures are at present unavailable, the Institute adopts 125° C. as a conservative limit for this class of insulation, and any increase above this figure should be the subject of special guarantee by the manufacturer.

190. Class C.—For fireproof and refractory materials, such as pure mica, porcelain, etc., no limit is specified.

191. When a lower-temperature class material is comprised in a completed product to such an extent, or in such ways, that its subjection to the temperature limits allowed for the higher-temperature class material, with which it is associated, would affect the integrity of the insulation either mechanically or electrically, the permissible temperature shall be fixed at such a value as shall afford ample assurance that no part of the lower-temperature class material shall be subjected to temperatures higher than those approved by the Institute and set forth above. See also §150.

192. **Table Summarizing the Temperature Conditions under the Three Preceding Methods of Measurement for Insulations of Classes A_1, A_2 and B.** (See next page.)

SPECIAL CASES OF TEMPERATURE LIMITS

193. **Temperature of Oil.** — The oil in which apparatus is immersed shall in no part be subjected to an observable temperature in excess of 90° C.

194. **Water-cooled Transformers.** — In these the hottest-spot temperature shall not exceed 85° C.

195. **Railway Motor Temperature Limits,** see §419.

196. **Squirrel-cage and Amortisseur Windings.** — In many cases the insulation of such windings is largely for the purpose of making the conductors fit tightly in their slots, and the slightest effective insulation is ample. In other cases there is practically no insulating material on the windings. Consequently, the temperature rise may be of any value such as will not occasion mechanical injury to the machine.

197. **Collector Rings.** — The temperature of collector rings shall not be permitted to exceed the "hottest-spot" values set forth in §188 for the insulations employed either in the collector rings themselves, or in adjacent insulations whose temperatures would be affected by the heat from the collector rings. The temperature of the rings shall in no case exceed 130° C.

198. **Commutators.** — For commutators so constructed that no difficulties from expansion can occur, the following temperature limits are prescribed:

Current per Brush Arm	Maximum Permissible Temp.
200 amperes or less	130° C.
200 to 900 amperes	130° C. less 5° for each 100 amperes increase above 200.
900 amperes and over	95° C.

In no case shall the observable temperature be permitted to exceed the values given in §188 for the insulation employed, either in the commutator or in any insulation whose temperature would be affected by the heat of the commutator.

199. **Cores.** — The temperature of the iron core in contact with the windings must not exceed the limits of temperature and temperature rise permitted for the windings themselves.

200. **Other Parts** (such as brush-holders, brushes, bearings, pole-tips, cores, etc.). All parts of electrical machinery other than those whose temperature affects the temperature of the insulating material, may be operated at such temperatures as shall not be injurious in any respect. But no part of continuous-duty machinery subject to handling in operation, such as brush-rigging, shall have a temperature in excess of 100° C. for more than a very brief time.

Class	Permissible Hottest-spot Temp.	Method I Thermometer only			Method II Resistance (With thermometer check when practicable)			Method III Imbedded thermocouples or resistance coils								
								Double-layer windings for all voltages			Single-layer windings 5000 volts or less			Single-layer windings above 5000 volts		
		Hottest-spot Correction	Limiting Observable Temp.	Limiting Temp. Rise above 40°	Hottest-spot Correction	Limiting Observable Temp.	Limiting Temp. Rise above 40°	Hottest-spot Correction	Limiting Observable Temp.	Limiting Temp. Rise above 40°	Hottest-spot Correction	Limiting Observable Temp.	Limiting Temp. Rise above 40°	Hottest-spot Correction	Limiting Observable Temp.	Limiting Temp. Rise above 40°
A_1	95°	15	80	40	10	85	45	5	90	50	10	85	45	10+(E-5)*	85−(E-5)	45−(E-5)
A_2	105°	15	90	50	10	95	55	5	100	60	10	95	55	10+(E-5)	95−(E-5)	55−(E-5)
B	125°	15	110	70	10	115	75	5	120	80	10	115	75	10+(E-5)	115−(E-5)	75−(E-5)

* In this formula *E* represents the rated pressure between terminals in kilovolts. Thus for a three-phase machine of 11 kilovolts between terminals the hottest-spot correction to be added to the maximum observable temperature will be 16°C.

ADDITIONAL REQUIREMENTS

201. **Short-circuit Stresses.** — The Institute recognizes the self-destructibility, both mechanical and thermal, of certain sizes and types of machines when subjected to severe short-circuits, and recommends that ample protection be provided in such cases, external to the machine if necessary.

202. **Over-Speeds.** — All types of rotating machines shall be so constructed that they will safely withstand an over-speed of 25 per cent, except in the case of steam turbines, which, when equipped with emergency governors, shall be constructed to withstand 20 per cent over-speed.

In the case of series motors, it is impracticable to specify percentage values for the guaranteed over-speed on account of the varying service conditions.

Water-wheel generators shall be constructed for the maximum runaway speed which can be attained by the combined unit.

203. **Momentary Loads.** — Machines shall be required to carry momentary loads of 150 per cent rated load, and commutating machinery shall commutate successfully under this condition. Successful commutation is such that neither brushes nor commutator are injured by the test.

Machines for Duty-cycle Operation shall be rated according to their equivalent load, either on the short-time or continuous basis, but intended for operation with widely fluctuating loads, shall commutate successfully under their specified operating conditions. See §139.

204. **Stalling Torque of Motors.** — Motors for continuous service shall, except when otherwise specified, be required to develop a running torque at least 175 per cent of that corresponding to the running torque at their rated load without stalling.

Obviously, duty-cycle machines must carry their peak loads without stalling.

WAVE FORM

205. **The Sine Wave** shall be considered as standard except where deviation therefrom is inherent in the operation of the machine.

206. **The Deviation of Wave Form** from the sinusoidal is determined by superposing upon the actual wave (as determined by oscillograph), the equivalent sine wave of equal length, in such a manner as to give the least difference, and then dividing the maximum difference between corresponding ordinates by the maximum value of the equivalent sine wave. A maximum deviation of the wave from sinusoidal shape not exceeding 10 per cent is permissible, except when otherwise specified.

EFFICIENCY AND LOSSES

207. **Machine Efficiency** is the ratio of the power delivered by the machinery to the power received by it.

208. **Plant Efficiency** is the ratio of the energy delivered from the plant to the energy received by it in the same period of time,* that period of time to be suitably chosen.

209. **Conventional Efficiency** of machinery is the ratio of the output to the sum of the output and the losses; or of the input minus the losses to the input; when, in either case, conventional values are assigned to one or more of these losses. The need for assigning conventional values to certain losses arises from the fact that some of the losses in electrical machinery are practicably

* An exception should be noted in the case of the efficiency of storage batteries.

indeterminable, and must, in many cases, either be approximated by an approved method of test, or else values recommended by the Institute and designated "conventional" values shall be employed for them in arriving at the "conventional efficiency." Efficiencies based upon conventional losses shall be specifically stated to be conventional efficiencies.

210. **Efficiency Determination.** — Input and output determination of efficiency may be made directly, measuring the output by brake, or equivalent, where applicable. Within the limits of practical application the circulating power method, sometimes described as the Hopkinson or "loading back" method, may be used; in machines where none of these methods are practicable the conventional efficiency should be used, especially in the case of large machines of high efficiency.

211. Values for the indeterminate losses may also be obtained by brake or other accurate test, and used in estimating actual efficiencies of similar machines, by the separate-loss method.

212. **Normal Conditions.** — The efficiency shall correspond to, or be corrected to, the normal conditions herein set forth, which shall be regarded as standard. These conditions include voltage, current, power-factor, frequency, wave shape, speed, temperature or such of them as may apply in each particular case.

213. **Measurement of Efficiency.** — Electric power shall be measured at the terminals of the apparatus. In polyphase machines sufficient measurements shall be made on all phases to avoid errors of unbalance.

214. **Point at Which Mechanical Power Shall be Measured.** — Mechanical power delivered by machines shall be measured at the pulley, gearing, or coupling, on the rotor shaft, thus excluding the loss of power in the belt or gear friction. See, however, §415.

215. **The Efficiency of Alternating-current Apparatus** shall be measured when the current is in phase with the terminal voltage, unless otherwise specified, or unless a definite phase difference is inherent in the apparatus, as in induction machinery.

216. **Efficiency of Alternating-current Apparatus in regard to Wave Shape.** — In determining the efficiency of alternating-current apparatus the sine wave is to be considered as standard, unless a different wave form is inherent in the operation of the apparatus. See §205.

217. **Temperature of Reference for Efficiency Determinations.** — The efficiency, at all loads, of all apparatus, shall be determined at, or corrected to, a reference temperature of 75° C.

218. **The Losses in Constant-potential Machinery,** either of the stationary type, or of the constant-speed rotary type, are of two classes; namely, those which remain substantially constant at all loads, and those which vary with the load. The former include iron losses, windage and friction, also I^2R losses in any shunt windings. The latter include I^2R losses in series windings. The constant losses may be determined by measuring the power required to operate the machine at no load, deducting any series I^2R losses. The variable loss at any load may be computed from the measured resistance of the series windings and the given load current.

219. **Stray Load-Losses.** — The above simple method of determining the losses and hence the efficiency is only approximate, since the losses which are assumed to be constant do actually vary to some extent with the load, and also because the actual loss in the copper windings is sometimes appreciably greater than the calculated I^2R loss. The difference between the approximate losses

as above determined and the actual losses is termed the "stray load-losses."* These latter are due to distortions in electric or magnetic fluxes from their no-load distributions or values, brought about by the load current. They are usually only approximately measurable or may be indeterminable.

220. Table of Losses. — Losses in apparatus may be classified as follows:

Accurately measurable or determinable	Approximately measurable or determinable	Indeterminable
a. No-load core losses including eddy-current losses in conductors at no-load	*c.* Brush friction loss	*h.* Iron loss due to flux distortion
b. Load I^2R in windings No load I^2R in windings	*d.* Brush-contact	*i.* Eddy-current losses in conductors due to transverse fluxes occasioned by the load currents
	e. Losses due to windage and to bearing friction	*k.* Eddy-current losses in conductors due to tooth saturation resulting from distortion of the main flux.
	f. Extra copper loss in transformer windings, due to stray fluxes caused by load currents	*l.* Tooth-frequency losses due to flux distortion under load
	g. Dielectric losses	*m.* Short-circuit loss of commutation

221. Evaluation of Losses. — The larger individual losses are either accurately or approximately determinable, but certain of the indeterminable losses reach values in various kinds of machinery which require that they should be taken into account.

Methods of measuring, approximating or allowing for these various losses are given below.

LOSSES TO BE TAKEN INTO ACCOUNT IN VARIOUS TYPES OF MACHINES

222. Continuous-current Commutating Motors and Generators.

No-load core-losses (Acc. Meas. or Deter.).

I^2R loss in windings (Acc. Meas. or Deter.).

Brush contact I^2R loss (Approx. Meas. or Deter.).

Unless otherwise specified, use the Institute Standard of 1 volt for contact drop per brush; — i.e., 2 volts for total brush drop — for either carbon or graphite brushes. See §§232 and **429.**

Friction of bearings and windage (Approx. Meas. or Deter.).

Rheostat losses, when present (Acc. Meas. or Deter.).

Brush friction (Approx. Meas. or Deter.).

All indeterminable load losses (including stray load iron losses) which may be important, which vary with the design, and for which no satisfactory method

* In the Table of §220 stray load-losses include *f, h, i, k, l* and *m*, but do not include increased core losses due to increased excitation for compensating internal drop under load.

of determination has been found, shall be included as zero per cent in estimating conventional efficiency.

223. Synchronous Motors and Generators.

No-load core-losses. (Acc. Meas. or Deter.)

I^2R loss in windings. (Acc. Meas. or Deter.) based upon rated kw. and power factor.

Stray load-losses. (Indeterminable). In approximating these losses, the method described in §236 shall be employed.

Friction of bearings and windage. (Approx. Meas. or Deter.) (Brush friction and brush-contact loss is negligible.)

Rheostat losses, when present (Acc. Meas. or Deter.) corresponding to rated kw. and power factor.

224. Induction Machines.

No-load core-losses. (Acc. Meas. or Deter.)

I^2R losses in windings. (Acc. Meas. or Deter.)

Stray load-losses. (Indeterminable.) In approximating these losses the method described in §240 shall be employed.

Brush friction when collector rings are present. (Approx. Meas. or Deter.)

Brush contact loss. (Approximately Meas. or Deter.) Unless otherwise specified, use the Institute Standard of 1 volt for contact drop per brush; — for either carbon or graphite brushes. See §232.

Friction of bearings and windage. (Approx. Meas. or Deter.)

225. Commutating A-C. Machines.

No-load core-losses. (Acc. Meas. or Deter.)

I^2R losses in windings. (Acc. Meas. or Deter.)

Brush friction. (Approx. Meas. or Deter.)

Brush contact loss. (Approx. Meas. or Deter.) Unless otherwise specified, use the Institute Standard of 1 volt for contact drop per brush; — for either carbon or graphite brushes. See §§232 and 429.

Friction of bearings and windage. (Approx. Meas. or Deter.)

Short-circuit loss of commutation. (Indeterminable.) Iron loss due to flux distortion. (Indeterminable.) Eddy-current losses due to fluxes varying with load and saturation. (Indeterminable.)	The Institute is not at this time prepared to make recommendations for approximating these losses.

226. Synchronous Converters.

No-load core-losses. (Acc. Meas. or Deter.)

I^2R losses in windings. (Approx. Meas. or Deter.) based on rated kw. and power factor.

Brush friction. (Approx. Meas. or Deter.)

Brush contact loss. (Approx. Meas. or Deter.) Unless otherwise specified, use the Institute Standard of 1 volt for contact drop per brush; — for either carbon or graphite brushes. See §232.

Short-circuit loss of commutation. (Indeterminable.) Iron loss due to flux distortion when present. (Indeterminate.) Eddy-current losses due to fluxes varying with load and saturation. (Indeterminable.)	These losses, while usually of low magnitude, are erratic, and the Institute is not at this time prepared to make recommendations for approximating them.

Friction of bearings and windage. (Approx. Meas. or Deter.)

For the booster type of synchronous converter, where the booster forms an integral part of the unit, its losses shall be included in the total converter losses in estimating the efficiency.

227. Transformers. — *No-load Losses.* These include the core-loss and the I^2R loss due to the exciting current (Acc. Meas. or Deter.) and the dielectric hysteresis loss in the insulation (Approx. Meas. or Deter.). At low power factors the total losses due to treating the exciting current in this way are likely to be too low.

Load-Losses.—These include I^2R loss in windings, and eddy-current losses in windings and core due to fluxes varying with load. (Approx. Meas. or Deter.) See §240 for the method of approximating these losses.

DETERMINATION OR APPROXIMATION OF LOSSES IN ROTATING MACHINERY

228. Bearing Friction and Windage may be determined as follows: Drive the machine from an independent motor, the output of which shall be suitably determined. The machine under test shall have its brushes removed and shall not be excited. This output represents the bearing friction and windage of the machine under test.

In the case of engine-type generators, one-half the output of the driving motor shall be charged against the generator for windage. The remainder, considered as bearing friction, shall be debited to the prime mover.

229. Brush Friction of Commutator and Collector Rings. — Follow the test of §228 taking an additional reading with the brushes in contact with the commutator or collector rings. The difference between the output obtained in the test in §228, and this output shall be taken as the brush friction. Note. — The surface of commutator and brushes should already be smooth and glazed from running when this test is made.

230. No-load Core-Loss. — Follow the test in §229 with an additional reading having the machine excited. The difference between the output value of §229 and the output value of this reading shall be taken as the no-load core-loss. This no-load core-loss shall be taken with the machine excited, so as to produce rated terminal voltage.

231. No-load Core-Loss at the Internal Voltage Corresponding to Rated Load. — This shall be taken as in §230, except that the machine shall be excited so as to produce at the terminals the voltage corresponding to the calculated internal voltage for the load and power factor under consideration. For synchronous machines, since no generally accepted method has been determined for obtaining the stator reactance, the internal voltage shall be determined by adding resistance drop to the terminal voltage.

232. Brush Contact Loss depends largely upon the material of which the brush is composed. As indicating the range of variation the following table will be of interest:

Grade of brush	Volts drop across one brush contact. (Average of positive and negative brushes)
Hard carbon	1.1
Soft carbon	0.9
Graphite	0.5 to 0.8
Metal-graphite types	0.15 to 0.5*

* The former for largest proportion of metal.

One volt drop per brush shall be considered as the Institute Standard drop corresponding to the I^2R brush-contact loss, for carbon and graphite brushes. Metal-graphite brushes, shall be considered as special. See §429.

233. **Field-rheostat Losses** which are normally present shall be included in the generator losses where there is a field rheostat in series with the field magnets of the generator, even when the machine is separately excited.

234. **Ventilating Blower.**—When a blower is supplied as part of the machine set, the power required to drive it shall be charged against the machine set; but not against the machine.

235. **Losses in Other Auxiliary Apparatus.** — Auxiliary apparatus, such as a separate exciter for a generator or motor, shall have its losses charged against the plant of which the generator and exciters are a part, and not against the generator.

236. **Stray Load-Losses in Synchronous Generators and Motors.** — These include iron losses and eddy-current losses in the copper due to fluxes varying with load and due to saturation.

Stray load-losses are to be determined by operating the machine on short-circuit and at rated-load current. This, after deducting the windage and friction and I^2R loss, gives the stray load-loss result thus obtained for polyphase generators and motors. These losses in single-phase machines are large; but the Institute is not yet prepared to give a method for measuring them.

237. **Stray Load-Losses in Induction Machines.** — These include eddy-current losses in the stator copper, and other eddy-current losses due to fluxes varying with the load. In wire-wound machines these are usually negligible.

With rotor removed and for a given stator current, measure the input through the stator at different frequencies. Plot a curve of loss against frequency. At low frequencies, the loss becomes constant, indicating the I^2R value. The difference between this I^2R value and the total loss at normal frequency shall be taken as the stray load-loss. This method is not accurate with induction motors in which the slots are entirely closed. In such machines these losses may be greater.

238. **Induction Motor Rotor I^2R Loss.** — This should be determined from the slip whenever the latter is accurately determinable, using the following equation:

$$\text{Rotor } I^2R \text{ loss} = \frac{\text{Output} \times \text{slip}}{1 - \text{slip}}.$$

In large slip-ring motors, in which the slip cannot be directly measured by loading, the rotor I^2R loss shall be determined by direct resistance measurement; the rotor full-load current to be calculated by the following equation:

$$\text{Current per ring} = \frac{\text{watts output.}}{\text{Rotor voltage at stand-still} \times \sqrt{3} \times K}.$$

This equation applies to three-phase rotors. For rotors wound for two phase use 2 instead of the $\sqrt{3}$. K may be taken as 0.95 for motors of 150 kw. or larger. The factor K usually decreases as the size of motor is reduced, but no specific value can be stated for smaller sizes.

DETERMINATION OR APPROXIMATION OF LOSSES IN TRANSFORMERS

239. **No-load Losses.** — These shall be measured with open secondary circuit at the rated frequency, and with an applied primary voltage giving the

rated secondary voltage plus the IR drop which occurs in the secondary under rated-load conditions. These no-load losses include core losses, consisting of hysteresis and eddy-current losses in the core, as well as dielectric loss in insulation due to electrostatic flux, which latter loss increases rapidly with temperature, and the test should therefore preferably be made at the reference temperature of 75° C.

240. **Stray Load-Losses.** — These shall be measured by applying a primary voltage sufficient to produce rated-load current in the primary and secondary windings, the latter being short-circuited. The stray load losses will then be equal to the input decreased by the measured I^2R losses in both windings. It is ordinarily immaterial whether the high-voltage or low-voltage winding is used as the primary winding in this test.

241. **Volt-ampere Ratio of Transformers.** — The volt-ampere ratio, which should not be confused with real efficiency, is the ratio of the volt-ampere output to the volt-ampere input of a transformer, at any given power factor.

242. **Methods of Loading Transformers for Temperature Tests.** — Wherever practicable, transformers should be tested under conditions that will give losses approximating as nearly as possible to those obtained under normal or specified load conditions, maintained for such a time as is necessary for the temperature to reach a steady value. The maximum temperature rises measured during this test should be considered as the observable temperature rises for the given load.

An approved method of making these tests is the "*loading back*" method. The principal variations of this method are:

243. (a) **With Duplicate Single-phase Transformers.** — Duplicate single-phase transformers may be tested in banks of two, with both primary and secondary windings connected in parallel. Normal magnetizing voltage should then be applied and the required current circulated from an auxiliary source. One transformer can be held under normal voltage and current conditions while the other may be operating under slightly abnormal conditions.

244. (b) **With One Three-phase Transformer.** — One three-phase transformer may be tested in a manner similar to (a), provided the primary and secondary windings are each connected in delta for the test. Normal three-phase magnetizing voltage should be applied and the required current circulated from an auxiliary single-phase source.

245. (c) **With Three Single-phase Transformers.** — Duplicate single-phase transformers may be tested in banks of three, in a manner similar to (b) by connecting both primary and secondary windings in delta and applying normal three-phase magnetizing voltage and circulating the required current from an auxiliary single-phase source.

246. **Note.** — Among other methods that have a limited application and can be used only under special conditions may be mentioned:

(1) Applying dead load by means of some form of rheostat.

(2) Running alternately for certain short intervals of time on open circuit and then on short-circuit, alternating in this way until the transformer reaches steady temperature.

In this test the voltage for the open-circuit interval and the current for the short-circuit interval shall be such as to give the same integrated core-loss, and the same integrated copper loss, as in normal operation.

DIELECTRIC TESTS OF MACHINERY

247. **Basis for Determining Test Voltages.** — The test voltage which shall be applied to determine the suitability of insulation for commercial operation is dependent upon the kind and size of the machinery, and its normal operating

voltage, upon the nature of the service in which it is to be used, and upon the severity of the mechanical and electrical stresses to which it may be subjected. The voltages and other conditions of test which are recommended have been determined as reasonable and proper for the great majority of cases and are proposed for general adoption, except when specific reasons make a modification desirable.

248. **Condition of Machinery to be Tested.**—Commercial tests shall, in general, be made with the completely assembled machinery and not with individual parts. The machinery shall be in good condition, and high-voltage tests, unless otherwise specified, shall be applied before the machine is put into commercial service, and shall not be applied when the insulation resistance is low owing to dirt or moisture. High-voltage tests shall be made at the temperature assumed under normal operation. High-voltage tests to determine whether specifications are fulfilled are admissible on new machines only. Unless otherwise agreed upon, high-voltage tests of a machine shall be understood as being made at the factory.

249. **Points of Application of Voltage.**—The test voltage shall be successively applied between each electric circuit and all other electrical circuits and metal parts grounded.

250. **Interconnected Polyphase Windings** are considered as one circuit. All windings of a machine, except that under test, shall be connected to ground.

251. **Frequency, Wave Form and Test Voltage.**—The frequency of the testing circuit shall not be less than the rated frequency of the apparatus tested. A sine-wave form is recommended. See §205. The test shall be made with alternating voltage having a crest value equal to the $\sqrt{2}$ times the specified test voltage.

252. **Duration of Application of Test Voltage.**—The testing voltage for all classes of apparatus shall be applied continuously for a period of 60 seconds.

253. **Apparatus for Use on Single-phase, 3-Phase-Delta or 3-Phase-Star Circuits.**—Apparatus, such as transformers, which may be used either on single-phase circuits, or in star or delta connection on three-phase circuits, shall have the maximum voltage of the circuits on which they may be used indicated on the rating plate and the test shall be based on such maximum voltage.

VALUES OF TEST VOLTAGES

254. **The Standard Test for all Classes of Apparatus, Except as Otherwise Specified, Shall be Twice the Normal Voltage of the Circuit to Which the Apparatus is Connected, Plus 1000 Volts.**

255. *Exception.*—**Alternating-current Apparatus connected to Permanently Grounded Single-phase Circuits, for use on Permanently Grounded Circuits of more than 3000 Volts** shall be tested with 2.73 times the voltage of the circuit to ground + 1000 volts.

256. *Exception.*—**Distributing Transformers.** Transformers for primary pressures from 550 to 5000 volts, the secondaries of which are directly connected to consumers' circuits and commonly known as distributing transformers, shall be tested with 10,000 volts from primary to core and secondary combined. The secondary windings shall be tested with twice their normal voltage plus 1000 volts.

257. *Exception.*—**Auto-Starter Transformers or Starting Compensators,** used for starting purposes, shall be tested with the same voltage as the test voltage of the apparatus to which they are connected.

258. *Exception.*—**Household Devices.** Apparatus taking not over 660* watts and intended solely for operation on supply circuits not exceeding 250 volts shall be tested with 900 volts.

259. *Exception.*—**Apparatus for Use on Circuits of 25 Volts or Lower,** such as bell-ringing apparatus,† electrical apparatus used in automobiles, apparatus used on low-voltage battery circuits, etc., shall be tested with 500 volts.

260. *Exception.*—**Field Windings of Alternating-current Generators** shall be tested with 10 times the exciter voltage, but in no case with less than 1500 volts.

261. *Exception.*—**Field Windings of Synchronous Machines,** including motors and converters requiring to be started from alternating-current circuits, shall be tested with 5000 volts, when the field is wound for 125 volts, and with 8000 volts when the field is wound for 250 volts or more. In no case shall the test voltage be lower than that given in §260.

262. *Exception.*—**Phase-wound Rotors of Induction Motors Required to Reverse in Service.** In order to allow for the extra voltage caused by the increased frequency at the instant of reversal, this test shall be four times stand-still voltage plus 1000.

263. *Exception.*—**Switches and Circuit Control Apparatus** above 600 volts, shall be tested with 2¼ times rated voltage plus 2000. See §§367 to 387.

264. *Exception.*—**Assembled Apparatus.** Where a number of pieces of apparatus are assembled together and tested as an electrical unit, they shall be tested with 15 per cent lower voltage than the lowest required on any of the individual pieces of apparatus.

265. **Testing Transformers by Induced Voltage.**—Under certain conditions it is permissible to test transformers by inducing the required voltage in their windings, in place of using a separate testing transformer. By required voltage, is meant a voltage such that the line end of the windings shall receive a test to ground equal to that required by the general rules.

266. **Transformers with Graded Insulation** shall be so marked. They shall be tested by inducing the required test-voltage in the transformer and connecting the successive line leads to ground.

MEASUREMENT OF VOLTAGE IN DIELECTRIC TESTS OF MACHINERY

267. **Use of Voltmeters and Spark-Gaps in Insulation Tests.**—When making insulation tests on electrical machinery, every precaution must be taken against the occurrence of any spark-gap discharges in the circuits from which the machinery is being tested. A non-inductive resistance of about one ohm per volt shall be inserted in series with one terminal of a spark gap. If the test is made with one electrode grounded, this resistance shall be inserted directly in series with the non-grounded electrode. If neither terminal is grounded, one-half shall be inserted directly in series with each electrode. In any case this resistance shall be as near the measuring gap as possible and not in series with the tested apparatus. This resistance will damp high-frequency oscillations at the time of breakdown and limit the current which will flow. A water tube is the most reliable resistance. Carbon resistors should not be used because their resistance becomes very low at high voltages.

* This rule does not include bell-ringing transformers of ratio 125 to 6 volts. See Code.
† The present Code power limit for a single outlet.

268. For Machinery of Low Capacitance.—When the machinery under test does not require sufficient charging current to distort the high-voltage wave shape, or change the ratio of transformation, the spark gap should be set for the required test voltage and the testing apparatus adjusted to give a voltage at which this spark gap just breaks down. This adjustment should be made with the apparatus under test disconnected. The apparatus should then be connected, and with the spark gap about 20 per cent longer, the testing apparatus is again adjusted to give the voltage of the former breakdown, which is the assumed voltage of test. This voltage is to be maintained for the required interval.

269. For Machinery of High Capacitance.—When the charging current of the machinery under test may appreciably distort the voltage wave, or change the effective ratio of the testing transformer referred to, the first adjustment of voltage with the gap set for the test voltage should be made with the apparatus under test connected to the circuit and in parallel with the spark gap.

When making arc-over tests of large insulators, leads, etc., partial arc-over of the tested apparatus may produce oscillations which will cause the measuring gap to discharge prematurely. The measured voltage will then appear too high. In such tests the "equivalent" ratio of the testing transformer should be measured by gap to within 20 per cent of the arc-over voltage of the tested apparatus with the tested apparatus in circuit. The measuring gap should then be greatly lengthened out and the voltage increased until the tested apparatus arcs over. This arc-over voltage should then be determined by multiplying the voltmeter reading by the equivalent ratio found above. Direct measurement of the spark-over voltage over one gap by another gap should always be avoided.

270. Measurements with Voltmeter.—In measuring the voltage with a voltmeter, the instrument should preferably derive its voltage from the high-tension circuit, either directly as with an electrostatic voltmeter, or through an auxiliary *ratio transformer*. It is permissible to measure the voltage at other places, such as the transformer primary, provided corrections can be made for the variations in ratio caused by the charging current of the machinery under test, or provided there is no material variation of this ratio. In any case, when the apparatus to be tested is insufficiently large in relation to the testing apparatus to cause wave distortion, the voltage must be checked by spark gap, as in §275.

A crest-voltage voltmeter has advantages over an r.m.s. voltage voltmeter in determining the maximum cyclic value of the testing e.m.f., since it eliminates the necessity for determining the crest factor of the e.m.f. wave.

271. Measurements with Spark Gaps.—If proper precautions are observed, spark gaps may be used to advantage in checking the calibration of voltmeters when set up for the purposes of high-pressure tests of the insulation of machinery.

272. Ranges of Voltages.—For such calibrating purposes:

The *Needle Spark-Gap* should preferably be used for voltages from 10 kv. to 50 kv. because of the larger air gaps involved.

A *Sphere Spark-Gap* should be used above 50 kv.

273. The Needle Spark-Gap.—The needle spark gap shall consist of new sewing needles supported axially at the ends of linear conductors which are at least twice the length of the gap. There must be a clear space around the gap for a radius of at least twice the gap length.

274. Sparking Distance.—The sparking distances in air between needle points for various root-mean-square sinusoidal voltages in mm. are as follows:

NEEDLE-POINT SPARK-OVER VOLTAGES WITH NO. OO SEWING NEEDLES

(At 25° C. and 760 mm. barometer)

R.M.S. kilovolts	Millimeters	R.M.S. kilovolts	Millimeters
10	11.9	40	62
15	18.4	45	75
20	25.4	50	90
25	33	60	118
30	41	70	149
35	51	80	180

The above values refer to a relative humidity of 80 per cent. Variations from this humidity may involve appreciable variations in the sparking distance.

275. **The Sphere Spark-Gap.**—The standard sphere spark-gap shall consist of two suitably mounted metal spheres.

No extraneous body or external part of the circuit shall be near the gap within twice the diameter of the spheres.

The shanks should not be greater in diameter than one-fifth the sphere diameter. Metal collars, etc., through which the shanks extend, should be as small as practicable and should not during any measurement come closer to the sphere than the maximum gap length used in that measurement.

The sphere diameter should not vary more than 0.1 per cent and the curvature, measured by a spherometer, should not vary more than 1 per cent from that of a true sphere of the required diameter.

All gaps are affected by barometric pressure and temperature, and if tests are not made at 25° C. and 760 millimeters barometer, appropriate corrections must be applied. The Institute is not at present prepared to make recommendations as to the amount of such correction.

The sparking distances between different spheres for various r.m.s. sinusoidal voltages will be assumed to be as follows:

276. SPHERE GAP SPARK-OVER VOLTAGES

(At 25° C. and 760 mm. barometer)

Kilo-volts	Sparking distance in millimeters					
	125-mm. spheres		250-mm. spheres		500-mm. spheres	
	One sphere grounded	Both spheres insulated	One sphere grounded	Both spheres insulated	One sphere grounded	Both spheres insulated
40	19.1	19.1				
50	24.4	24.4				
60	30	30	29	29		
70	36	36	35	35		
80	42	42	41	41	41	41
90	49	49	46	45	46	45
100	56	55	52	51	52	51
120		71	64	63	63	62
140		88	78	77	74	73
160		110	92	90	85	83
180			109	106	97	95
200			128	123	108	106
220			150	141	120	117
240			177	160	133	130
260					148	144
280					163	158
300					177	171
320					194	187
340					214	204
360					234	221

The sphere gap is more sensitive than the needle gap to momentary rises of voltage, and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage, or by slowly raising the voltage with a fixed setting of the gap.

INSULATION RESISTANCE OF MACHINERY

277. **The Insulation Resistance of a Machine** at its operating temperature shall be not less than that given by the following formula:
Insulation resistance in megohms =

$$\frac{\text{voltage at terminals}}{\text{rated capacity in kv-a.} + 1000}.$$

The formula only applies to dry apparatus. Such high values are not attainable in oil-immersed apparatus.

Insulation resistance tests shall, if possible, be made at a d-c. pressure of 500 volts. Since the insulation resistance varies with the pressure, it is necessary that, if a pressure other than 500 volts is to be employed in any case, this other pressure shall be clearly specified.

The order of magnitude of the values obtained by this rule is shown in the following table:

Rated voltage of machine	Megohms		
	100 kv-a.	1000 kv-a.	10,000 kv-a.
100	0.091	0.05	——
1,000	0.91	0.50	0.091
10,000	9.1	5.0	0.91
100,000	——	50	9.1

278. It should be noted that the insulation resistance of machinery is of doubtful significance by comparison with the dielectric strength. The insulation resistance is subject to wide variation with temperature, humidity and cleanliness of the parts. When the insulation resistance falls below that corresponding to the above rule, it can in most cases of good design, and where no defect exists, be brought up to the required standard by cleaning and drying out the machine. The insulation resistance test may therefore afford a useful indication as to whether the machine is in suitable condition for the application of the dielectric test.

REGULATION

DEFINITIONS

279. **Regulation.**—The regulation of a machine in regard to some characteristic quantity (such as terminal voltage or speed) is the change in that quantity occurring between any two loads. Unless otherwise specified, the two loads considered shall be zero load and rated load and at the temperature attained under normal operation. The regulation may be expressed by stating the numerical values of the quantity at the two loads, or it may be expressed by the "percentage regulation" which is the percentage ratio of the change in the quantity occurring between the two loads to the value of the quantity at either one or the other load, taken as the normal value. It is assumed that all parts of the machine affecting the regulation maintain constant temperature between the two loads, and where the influence of temperature is of consequence, a reference temperature of 75° C. shall be considered as standard. If change of temperature should occur during the tests the results shall be corrected to the reference temperature of 75° C.

The normal value may be either the no-load value, as the no-load speed of induction motors; or it may be the rated-load value as in the voltage of a-c. generators.

It is usual to state the regulation of d-c. generators by giving the numerical values of the voltage at no load and rated load, and in some cases it is advisable to state regulation at intermediate loads.

280. **The Regulation of D-C. Generators** refers to changes in voltage corresponding to gradual changes in load and does not relate to the comparatively large momentary fluctuations in voltage that frequently accompany instantaneous changes in load.

In determining the regulation of a compound-wound d-c. generator, two tests shall be made, one bringing the voltage down and the other bringing the voltage up between no load and rated load. These may differ somewhat, owing to residual magnetism. The mean of the two results shall be used.

281. In Constant-potential A-C. Generators, the regulation is the rise in voltage (when the specified load at specified power factor is thrown off) expressed in per cent of normal rated-load voltage.

282. In Constant-current Machines, the regulation is the ratio of the maximum difference of current from the rated-load value (occurring in the range from rated load to short-circuit, or minimum limit of operation), to the rated-load current.

283. In Constant-speed Direct-current Motors, and induction motors, the regulation is the ratio of the difference between full-load and no-load speeds to the no-load speed.

284. In Constant-potential Transformers, the regulation is the difference between the no-load and rated-load values of the secondary terminal voltage at the specified power factor (with constant primary impressed terminal voltage) expressed in per cent of rated-load secondary voltage, the primary voltage being adjusted to such a value that the apparatus delivers rated output at rated secondary voltage.

285. In Converters, Dynamotors, Motor-generators and Frequency Converters, the regulation is the change in the terminal voltage of the output side between the two specified loads. This may be expressed by giving the numerical values or as the percentage ratio.

286. In Transmission Lines, Feeders, etc., the regulation is the change in the voltage at the receiving end between rated non-inductive load and no load, with constant impressed voltage upon the sending end. The percentage regulation is the percentage change in voltage to the normal rated voltage at the receiving end.

287. In Steam Engines, Steam Turbines and Internal Combustion Engines, the percentage speed regulation is usually expressed as the percentage ratio of the maximum variation of speed to the rated-load speed in passing slowly from rated load to no load (with constant conditions at the supply).

288. Fluctuation. — If the test is made by passing suddenly from rated load to no load, the immediate percentage speed regulation so derived shall be termed the fluctuation.

289. In a Hydraulic Turbine, or other water motor, the percentage speed regulation is expressed as the percentage ratio of the maximum variation in speed in passing slowly from rated load to no load (at constant head of water), to the rated-load speed.

290. In a Generator Unit consisting of a generator combined with a prime mover, the speed or voltage regulation should be determined at constant conditions of the prime mover, i.e., constant steam-pressure, head, etc. It includes the inherent speed variations of the prime mover. For this reason the regulation of a generator unit is to be distinguished from the regulation of either the prime mover, or of the generator combined with it, when taken separately.

CONDITIONS FOR TESTS OF REGULATION

291. Speed and Frequency. — The regulation of generators is to be determined at constant speed, and of alternating-current apparatus at constant frequency.

292. Power Factor. — In apparatus generating, transforming or transmitting alternating currents, the power factor of the load to which the regulation refers should be specified. Unless otherwise specified, it shall be understood as referring to non-inductive load, that is to a load in which the current is in phase with the e.m.f. at the output side of the apparatus.

293. **Wave Form.** — In the regulation of alternating-current machinery receiving electric power, a sine wave of voltage is assumed, except where expressly specified otherwise. See §205.

294. **Excitation.** — In commutating machines, rectifying machines and synchronous machines, such as direct-current generators and motors, as well as in alternating-current generators, the regulation is to be determined under the following conditions, so as to maintain the field adjustment constant at that which gives rated-load voltage at rated-load current.

(1) In the case of separately excited field magnets, constant excitation.

(2) In the case of shunt machines, constant resistance in the shunt-field circuit.

(3) In the case of series or compound machines, constant resistance shunting the series-field windings.

295. **Tests and Computation of Regulation of A-C. Generators.** — Any one of the three following methods may be used. They are given in the order of preference.

Method (a). — The regulation can be measured directly by loading the generator at the specified load and power factor, then reducing the load to zero, and measuring the terminal voltage, with speed and excitation adjusted to the same values as before the change. This method is not generally applicable for shop tests, particularly on large generators, and it becomes necessary to determine the regulation from such other tests as can be readily made.

296. **Method (b).** — This consists in computing the regulation from experimental data of the open-circuit saturation curve and the zero-power factor saturation curve. The latter curve, or one approximating very closely to it, can be obtained by running the generator with over-excited field on a load of idle-running under-excited synchronous motors. The power factor under these conditions is very low and the load saturation curve approximates very closely the zero power factor saturation curve. From this curve and the open circuit curve, points for the load saturation curve for any power factor can be obtained by means of vector diagrams.

To apply method (b), it is necessary to obtain from test, the open-circuit saturation curve OA, Fig. 1, and the saturation curve BC at zero power factor and rated-load current. At any given excitation Oc, the voltage that would be induced on open circuit is ac, the terminal voltage at zero power factor is bc, and the apparent internal drop is ab. The terminal voltage dc at any other power factor can then be found by drawing an e.m.f. diagram * as in Fig. 2, where ϕ is an angle such that $\cos\phi$ is the power factor of the load, be the resistance drop (IR) in the stator winding, ba the total internal drop and ac the total induced voltage, ba and ac being laid off to correspond with the values obtained from Fig. 1. The terminal voltage at power factor $\cos\phi$ is then cb

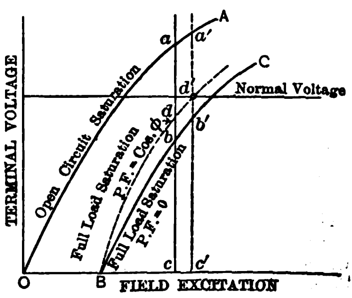

Fig. 1

* Method b, for deducing the load saturation curve, at any assigned power factor, from no-load and zero-power-factor saturation curves obtained by test, must be regarded as empirical. Its value depends upon the fact that experience has demonstrated the reasonable correctness of the results obtained by it.

of Fig. 2 which, laid off in Fig. 1, gives point d. By finding a number of such points, the curve Bdd' for power factor $\cos\phi$ is obtained and the regulation at this power factor (expressed in per cent) is $\frac{100 \times a'd'}{d'c'}$, since $a'd'$ is the rise in voltage when the load at power factor $\cos\phi$ is thrown off at normal voltage $c'd'$.

Generally, the ohmic drop can be neglected, as it has very little influence on the regulation, except in very low-speed machines, where the armature resistance is relatively high, or in some cases where regulation at unity power factor is being estimated; for low power factors, its effect is negligible in practically all cases. If resistance is neglected, the simpler e.m.f. diagram, Fig. 3, may be used to obtain points on the load saturation curve for the power factor under consideration.

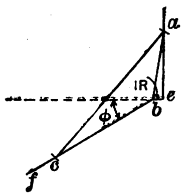

Fig. 2

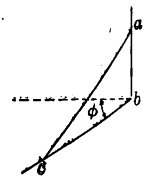

Fig. 3

297. Method (c).—Where it is not possible to obtain by test a zero-power-factor saturation curve as in (b), this curve can be estimated closely from open-circuit and short-circuit curves, by reference to tests at zero power factor on other machines of similar magnetic circuit. Having obtained the estimated zero-power-factor curve, the load saturation for any other power factor is obtained as in (b).

Thus Method (c) is the same as (b), except that the zero-power-factor curve must be estimated. This may be done as follows: In Fig. 4 OA is the open-circuit saturation curve and OE the short-circuit line as shown by test. The zero-power factor curve corresponding to any given current BF will start from point B and for machines designed with low saturation and low reactance will follow parallel to OA, as shown by the dotted curve BD which is OA shifted parallel to itself by the distance OB. In high-speed machines, or in others having low reactance and a low degree of saturation in the magnetic circuit, the zero-power-factor curve will lie quite close to BD, particularly in those parts that are used for determining the regulation. This is the case with many turbo-generators or high-speed water-wheel generators. In many cases, however, the zero-power-factor curve will deviate from BD, as shown by BC, and the deviation will be most pronounced in machines of high reactance, high saturation and large magnetic leakage. The position of the actual curve BC with relation to BD can be approximated with sufficient exactness by investigating the corresponding relations as obtained by test at zero power factor on machines of similar characteristics and magnetic circuit. Or curve BC can be calculated by methods based on the results of tests at zero power factor. After BC has been obtained, the saturation curve and regulation for any other power factor can be derived as in Method (b).

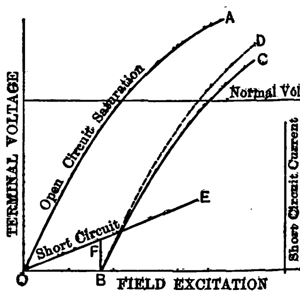

Fig. 4

298. **Tests and Computation of Regulation for Constant-potential Transformers.**—The regulation can be determined by loading the transformer and measuring the change in voltage with change in load at the specified power factor. This method is not generally applicable for shop tests, particularly on large transformers.

The regulation for any specified load and power factor can be computed from the percentage resistance drop and percentage reactance drop in the windings as follows:

299. To compute the regulation of a constant-potential transformer, it is necessary to obtain the equivalent resistance R and impedance drop E_z. The equivalent resistance R of primary and secondary combined is found by multiplying the secondary resistance by the square of the ratio of turns and adding it to the primary resistance. The impedance voltage E_z is found by short-circuiting the secondary winding and measuring the volts necessary to send rated-load current through the primary.

300. The reactance drop is then

$$IX = \sqrt{E_z^2 - \left(\frac{P}{I}\right)^2}$$

where P = impedance watts as measured in the short-circuit test.

Let

E = rated primary voltage,
IR = resistance drop in volts,
IX = reactance drop in volts,

$$q_r = 100\,\frac{IR}{E} = \text{per cent resistance drop,}$$

$$q_x = 100\,\frac{IX}{E} = \text{per cent reactance drop.}$$

301. Then

(1) For unity power factor,

$$\text{Per cent regulation} = q_r + \frac{q_x^2}{200}.$$

302. (2) For inductive loads of power factor m and reactive factor n,

$$\text{Per cent regulation} = mq_r + nq_x + \frac{(mq_x - nq_r)^2}{200}.$$

TRANSFORMER CONNECTIONS, SINGLE-PHASE TRANSFORMER

303. **Marking of Leads.**—The leads of single-phase transformers shall be distinguished from each other by marking the high-voltage leads with the letters A and B, and the low-voltage leads with the letters X and Y. They shall be so marked that the potential difference between A and B shall have the same direction at any instant as the potential difference between X and Y.

In accordance with the above rule, the terminals of single-phase transformers shall be marked as follows:

304. (1) High- and low-voltage windings in phase:

$$\begin{array}{c} A \text{———} B \\ X \text{———} Y \end{array}$$

305. (2) High- and low-voltage windings 180 deg. apart in phase:

$$\begin{matrix} A \text{———} B \\ Y \text{———} X \end{matrix}$$

306. To operate transformers thus marked in parallel, it is only necessary to connect similarly marked terminals together (provided that the reactances and resistances of the transformers are such as to permit of parallel operation).

307. Single-phase Transformers with More than Two Windings.—Transformers possessing three or more windings (each being provided with separate outgoing leads) shall have the leads connected to two of their windings, lettered in accordance with the preceding paragraph. The remaining leads shall be distinguished from the others by a subscript. For example, transformers possessing four secondary leads connected to two distinct similar windings for multiple-series operation, shall be lettered as follows:

$$\begin{matrix} A \text{———} B \\ \left\{\begin{matrix} X \text{———} Y \\ X_1 \text{———} Y_1 \end{matrix}\right\} \end{matrix}$$

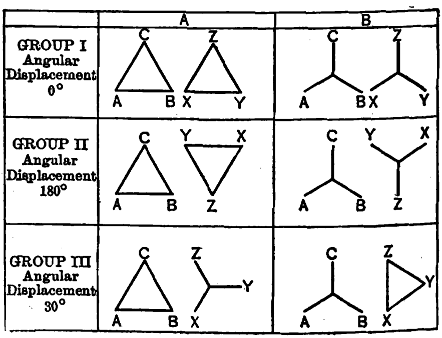
This indicates that the low-voltage winding consists of two disconnected parts, one part having terminals XY and the other part having terminals X_1Y_1. For multiple connection, X and X_1 are connected together and Y and Y_1 are connected together. For series connection, Y is connected to X_1.

308. Neutral Lead.—An outgoing 50 per cent (neutral) tap lead should be lettered N.

309. Internal Connections.—The manufacturer shall furnish a complete diagrammatic sketch of internal connections, and all taps and terminals of the transformer shall be marked to correspond with numbers or letters in the sketch.

THREE-PHASE TRANSFORMERS

310. Three-phase transformers ordinarily have three or four leads for high-voltage, and three or four leads for low-voltage windings. To distinguish the various leads from each other, and also to distinguish between the various phase relations obtainable, the three high-voltage leads should be lettered ABC and the three low-voltage leads XYZ. In addition, it should be distinctly stated in which of the three groups given in the accompanying diagram the transformer belongs.



The rules given above for single-phase transformers in regard to the neutral tap, and also in regard to internal connections, are applicable to three-phase transformers.

311. Angular Displacement.—The angular displacement between high- and low-voltage windings is the angle in the accompanying diagram, the lines passing from a neutral point through A and X respectively. Thus, in Group I,

the angular displacement is zero degrees. In Group 2, the angular displacement is 180°, and in Group 3 the angular displacement is 30°.

312. **Parallel Operation of Three-phase Transformers.** — Three-phase transformers, lettered in accordance with the above rules, will operate correctly in parallel, if their percentage resistance drops are equal, and their percentage reactance drops, at their rated loads, are equal. It is furthermore necessary that the angular displacements between high-voltage and low-voltage windings shall be equal, i.e., that the transformers shall belong to the same group in the accompanying diagram. It is then only necessary to connect together similarly marked leads.

INFORMATION TO BE GIVEN ON THE RATING PLATE OF A MACHINE*

313. (a) It is recommended that the rating plate of machines which comply with the Institute rules shall carry a distinctive special sign, such as "A.I.E.E. Rating."

(b) The absence of any statement to the contrary on the rating plate of a machine implies that it is intended for continuous service and for the standard ambient temperature of reference. See §§153 and 157.

(c) The rating plate of a machine intended to work under various kinds of rating must carry the necessary information in regard to those kinds of ratings.

(d) The rating plate, in addition to the name of the manufacturer and the serial number, must give the following information. See also §§391 and 415.

314. **Generator, Direct-current.**
Shunt, series, or compound.
Output, in kw., with statement as to the kind of rating.
Terminal pressure, in volts.
Current, in amperes.
Speed, in revolutions per minute.

315. **Motor, Direct-current.**
Shunt, series or compound.
Output, in kw., with statement as to the kind of rating.
Terminal pressure, in volts.
Current, approximate, in amperes.
Speed, in revolutions per minute.

316. **Transformer.**
Frequency, in cycles per second.
Number of phases.
Output at the secondary terminals in kv-a., with statement as to the kind of rating.
Primary pressure, in volts.
Secondary pressure, in volts. See §110.
Lead markings and diagram of internal connections as stated in §§303 to 312.

317. **Alternator.**
Frequency, in cycles per second.
Number of poles.
Number of phases.
Output, in kv-a., with statement as to the kind of rating and power factor corresponding to rated output.
Pressure between terminals, in volts, corresponding to the rated output.

*Information, for which space on the rating plate cannot be provided, shall be furnished on a subsidiary rating certificate.

Current in amperes.
Speed in revolutions per minute.
Excitation pressure, in volts.
Maximum exciting current, in amperes, required to maintain rated voltage under rated load.

318. **Synchronous Motor.**
Frequency, in cycles per second.
Number of poles.
Number of phases.
Mechanical output, in kw., with statement as to the kind of rating.
Pressure between terminals, in volts, corresponding to the rated output.
Current in amperes.
If the motor is intended to work with a power factor different from unity the necessary information shall be given.
Speed, in revolutions per minute.
Excitation pressure, in volts.
Maximum exciting current, in amperes, required to maintain rated power factor under rated load.

319. **Synchronous Converter.**
Frequency in cycles per second.
Number of poles.
Shunt or compound.
Number of phases.
Output at commutator in kilowatts, with statement as to kind of rating. In case of a converter for railroad service, both nominal and continuous ratings.
A-c. terminal pressure in volts.
D-c. terminal pressure in volts.
Current from commutator in amperes.
Speed in revolutions per minute.

320. **Induction Motor.**
Frequency, in cycles per second.
Number of poles.
Number of phases.
Mechanical output, in kw., with statement as to the kind of rating.
Pressure between terminals, in volts.
Current, in amperes.
Speed, in revolutions per minute, at rated output.
Secondary pressure (initial) when starting.

STANDARDS FOR WIRES AND CABLES

321-337. **Terminology.**—Same as in *Circular No. 37 of the Bureau of Standards. Given in full in the article on Wires and Cables, Insulated.*

SPECIFICATION OF SIZES OF CONDUCTORS

338. The sizes of solid wires shall be stated by their diameter in mils, the American Wire Gage (Brown and Sharpe) sizes being taken as standard. The sizes of stranded conductors shall be stated by their cross-sectional area in circular mils. For brevity, in cases where the most careful specification is not required, the sizes of solid wires may be stated by the gage number in the American Wire Gage, and the sizes of stranded conductors smaller than 250,000 circular mils (i.e., No. 0000 A.W.G. or smaller) may likewise be

stated by means of the gage number in the American Wire Gage of a solid wire having the same cross-sectional area. Furthermore, an exception is made in the case of "Flexible Stranded Conductors," for which see §341 below. In stating large cross-sections, it is sometimes convenient to use a circular inch (507 sq. mm.) instead of 1,000,000 circular mils.

STRANDING

339. The Standard Concentric Stranding Table printed in Circulars 31 and 37 of the Bureau of Standards, is adopted.

STANDARDIZATION OF CONCENTRIC STRANDING

Range of sizes		Number of wires. Standard concentric-lay cables
Circular mils	Sq. mm.	
2,000,000 to 1,600,000	1015 to 810	127
1,500,000 to 1,100,000	760 to 560	91
1,000,000 to 550,000	507 to 280	61
500,000 to 250,000	253 to 127	37
No. 0000 to No. 1 A.W.G.	107 to 42	19
No. 2 and smaller	33	7

340. **Sectional Area of Cables.**—The cross-sectional area of a cable shall be considered to be the sum of the cross-sectional areas of its component wires, when laid out straight and measured perpendicular to their axes.

341. **Flexible Stranding.**—Conductors of special flexibility should ordinarily be made with wires of regular A.W.G. sizes, the number of wires and size being given. The approximate gage number or approximate circular mils of such flexible stranded conductors may be stated.

342. **Correction for Lay.**—The resistance and mass of a stranded conductor are greater than in a solid conductor of the same cross-sectional area, depending on the lay (i.e., the pitch of the twist of the wires). Two per cent shall be taken as the standard increment of resistance and of mass. In cases where the lay is definitely known, the increment should be calculated and not assumed.

The direction of lay is the lateral direction in which the strands of a cable run over the top of the cable as they recede from an observer looking along the axis of the cable.

CONDUCTIVITY OF COPPER

343. The following I.E.C. rules are adopted:*

The following shall be taken as normal values for standard annealed copper:

(1) At a temperature of 20° C., the resistance of a wire of standard annealed copper one meter in length and of a uniform section of 1 square millimeter is 1/58 ohm = 0.017241... ohm.

(2) At a temperature of 20° C. the density of standard annealed copper is 8.89 grams per cubic centimeter.

* See I. E. C. Publication No. 28 "International Standard of Resistance for Copper," March, 1914.

(3) At a temperature of 20° C., the "constant mass" temperature coefficient of resistance of standard annealed copper, measured between two potential points rigidly fixed to the wire, is 0.00393 = 1/254.45...per degree centigrade.

(4) As a consequence, it follows from (1) and (2) that, at a temperature of 20° C. the resistance of a wire of standard annealed copper of uniform section, one meter in length and weighing one gram, is $(1/58) \times 8.89 = 0.15328\ldots$ ohm.*†

344. Copper Wire Tables.—The copper-wire tables published by the Bureau of Standards in Circular No. 31 are adopted. These Tables are based upon the I.E.C. rules stated in §343.

HEATING AND TEMPERATURE OF CABLES

345. Maximum Safe Limiting Temperatures.—The maximum safe limiting temperature in degrees Cent. at the surface of the conductor in a cable shall be:

For impregnated paper insulation	$(85 - E)$,
For varnished cambric	$(75 - E)$,
For rubber insulation	$(60 - 0.25\,E)$,

where E represents the r.m.s. operating e.m.f. in kilovolts between conductors.

Thus, at a working pressure of 3.3. kv., the maximum safe limiting temperature at the surface of the conductor or conductors in a cable would be:

For impregnated paper	81.7° C,
For varnished cambric	71.7° C,
For rubber	59.2° C.

ELECTRICAL TESTS OF CABLES

346. Lengths Tested.—Electrical tests of insulation on wires and cables shall be made on the entire length to be shipped.

347. Immersion in Water.—Electrical tests of insulated conductors not enclosed in a lead sheath shall be made while immersed in water after an immersion of twelve (12) hours, if insulated with rubber compound, or if insulated with varnished cambric. It is not necessary to immerse in water insulated conductors enclosed in a lead sheath.

In multiple-conductor cables, without waterproof over-all jacket of insulation, no immersion test should be made on finished cables, but only on the individual conductors before assembling.

348. Dielectric-strength Tests. Object of Tests.—Dielectric tests are intended to detect weak spots in the insulation and to determine whether the dielectric strength of the insulation is sufficient to enable it to withstand the voltage it is likely to be subjected to, in service, with a suitable factor of assurance.

The initially-applied voltage must not be greater than the working voltage, and the rate of increase shall not be over 100 per cent in 10 seconds.

* Paragraphs (1) and (4) of §343 define what are sometimes called "volume resistivity," and "mass-resistivity" respectively. This may be expressed in other units as follows:—volume resistivity = 1.7241 microhm-cm. (or microhms in a cm. cube) at 20° C. = 0.67879 microhm-inch at 20° C., and mass resistivity = 875.20 ohms (mile, pound) at 20° C.

† For detailed specifications of commercial copper, see the "Standard Specifications" of the American Society for Testing Materials.

349. **Factor of Assurance.** — The factor of assurance of wire or cable insulation shall be the ratio of the voltage at which it is tested to that at which it is used.

350. **Test Voltage.** — The dielectric strength of wire and cable insulation shall be tested at the factory by applying an alternating test voltage between the conductor and sheath or water.

351. **The Magnitude and Duration of the Test Voltage** should depend upon the dielectric strength and thickness of the insulation, the length and diameter of the wire or cable, and the assurance factor required, the latter in turn depending upon the importance of the service in which the wire or cable is employed.

The following test voltages shall apply unless the departure is considered necessary in view of the above circumstances. Rubber-covered wires or cable for voltages up to 7 kv. shall be tested in accordance with the National Electric Code. Standardization for higher voltages for rubber insulated cables is not considered possible at the present time.

Varnish cambric and impregnated paper insulated wires or cables shall be tested at the place of manufacture for five (5) minutes in accordance with the table given below.

Different engineers specify different thickness of insulation for the same working voltages. Therefore, at the present time the test kv. corresponding to working kv. given in the table below are based on the *minimum* thickness of insulation specified by engineers and operating companies.

RECOMMENDED TEST KILOVOLTS CORRESPONDING TO OPERATING KILOVOLTS

Operating kv.	Test kv.	Operating kv.	Test kv.
0.5	2.5*	5	14
0.5	3	10	25
1	4	15	35
2	6.5	20	44
3	9	25	53
4	11.5		

* For minimum insulation thickness of 1/16 inch.

352. **The Frequency of the Test Voltage** shall not exceed 100 cycles per second, and should approximate as closely as possible to a sine wave. The source of energy should be of ample capacity.

353. **Where Ultimate Break-down Tests** are required, these shall be made on samples not more than 6 meters (20 ft.) long. The maximum allowable temperature at which the test is made for the particular type of insulation and the particular working pressure, shall not be greater than the temperature limits given in §345.

354. **Multiple-conductor Cables.** — Each conductor of a multiple-conductor cable shall be tested against the other conductors connected together with the sheath or water.

INSULATION RESISTANCE

355. **Definition.** — The insulation resistance of an insulated conductor is the electrical resistance offered by its insulation, to an impressed voltage tending to produce a leakage of current through the same.

356. Insulation resistance shall be expressed in megohms for a specified length (as for a kilometer, or a mile, or one thousand feet), and shall be corrected to a temperature of 15.5° C. using a temperature coefficient determined experimentally for the insulation under consideration.

357. Linear insulation resistance, or the insulation resistance of unit length, shall be expressed in terms of the megohm-kilometer, or the megohm-mile, or the megohm-thousand-feet.

358. Megohms Constant.—The megohms constant of an insulated conductor shall be the factor "K" in the equation

$$R = K \log_{10} \frac{D}{d}$$

where R = the insulation resistance, in megohms, for a specified unit length, D = outside diameter of insulation, d = diameter of conductor. Unless otherwise stated, K will be assumed to correspond to the mile unit of length.

359. Test.—The apparent insulation resistance should be measured after the dielectric-strength test, measuring the leakage current after a one-minute electrification, with a continuous e.m.f. of from 100 to 500 volts, the conductor being maintained positive to the sheath or water.

360. Multiple-conductor Cables.—The insulation resistance of each conductor of a multiple-conductor cable shall be the insulation resistance measured from such conductor to all the other conductors in multiple with the sheath or water.

CAPACITANCE OR ELECTROSTATIC CAPACITY

361. Capacitance is ordinarily expressed in microfarads. Linear capacitance, or capacitance per unit length, shall be expressed in microfarads per unit length (kilometer, or mile, or one thousand feet) and shall be corrected to a temperature of 15.5° C.

362. Microfarads Constant.—The microfarads constant of an insulated conductor shall be the factor "K" in the equation.

$$C = \frac{K}{\log_{10} \frac{D}{d}},$$

where C = the capacitance in microfarads per unit length, D = the outside diameter of insulation, d = the diameter of conductor. Unless otherwise stated, K will be assumed to refer to the mile unit of length.

363. Measurement of Capacitance.

For Low-voltage Cable.—The capacitance shall be measured by comparison with a standard condenser. For long lengths of high-voltage cables, where it is necessary to know the true capacitance, the measurement should be made at a frequency approximating the frequency of operation.

364. Paired Cables.—The capacitance shall be measured between conductors of pairs, the other wires being connected to the sheath or ground.

365. Electric Light and Power Cables.—The capacitance of low-voltage cables is generally of but little importance. The capacitance of high-voltage cables should be measured between the conductors and also between each conductor and the other conductors connected to the lead sheath or ground.

366. **Multiple-conductor Cables** (not paired). The capacitance of each conductor of a multiple conductor cable shall be the capacitance measured from such conductor to all of the other conductors in multiple with the sheath or the ground.

RATING AND TESTING OF SWITCHES AND OTHER CIRCUIT-CONTROL APPARATUS

SWITCHES

367. The following rules apply to **Switches** of above 600 volts. (For 600 volts and below, see Code.*)

Definition. — A device for making, breaking or changing connections in an electric circuit.

368. **Rating.** — (a) By amperes to be carried with not more than 30° C. rise on contacts and current-carrying parts. (b) By normal voltage of circuit on which it may be used.

369. **Performance and Tests.**

(a) **Heating Test** with rated current applied continuously until temperature is constant; ambient temperature 40° C.

(b) **Dielectric Test** at 2¼ times rated voltage plus 2000. See §263.

CIRCUIT BREAKERS

370. **Definition.** — A device designed to open a current-carrying circuit without injury to itself. A circuit breaker † may be:

(a) An automatic circuit breaker, which is designed to trip automatically under any predetermined condition of the circuit, such as an underload or overload of current or voltage.

(b) A manually-tripped circuit breaker, which is designed to be tripped by hand.

Both types of operation may be combined in one and the same device.

371. **Rating.** — (a) By normal current-carrying capacity. (b) By normal voltage. (c) By amperes which it can interrupt at normal voltage of the circuit.

372. **Performance and Tests.** — The heating test shall be made with normal current; in oil circuit breakers, same oil must be used for heating tests as for rupturing tests. Rise on contacts not to exceed 30° C. Rise on tripping solenoids and accessory parts not to exceed 50° C. Ambient temperature of reference, 40° C.

373. **Dielectric Test.** Same as §369.

374. **Rupturing Test** must be made with the current specified under §371 (c), and at normal voltage.

NOTE. — Although circuit breakers should be considered as devices alone, no account being taken, in the rating, of the system on which they are to be used; yet in applying circuit breakers to any given service, it may be necessary to take into account the system on which they are to be used, with all its characteristics.

* By the term "Code" is meant "National Electrical Code" as recommended by the National Fire Protection Association.

† These rules refer only to circuit breakers of above 550 volts For 550 volts and below, see Code.

Allowances must be made for the reactance, resistance, etc., of the circuit to be controlled, as these have a direct bearing on the maximum current flow.

In some systems it has been found that the pressure rises so high during switching that higher insulation tests than that specified in §369 should be given.

FUSES

(For circuits up to and including 600 volts, see Code.)

NOTE. — Complete standardization of these fuses above 600 volts according to the method of the Code is not advisable at this time, but is expected to be accomplished by an eventual extension of the Code. Until such extension is made the following definitions and ratings may be followed.

375. **Definition.** — An element designed to melt or dissipate at a predetermined current value and intended to protect against abnormal conditions of current.

NOTE. — The terminals, tubes, etc., which go with the fuse proper are included in the definition.

376. **Rating.** — Fuses shall be rated at the maximum current which they are required to carry continuously and at the normal voltage of the circuit on which they are designed to be used.

Fuses may be divided into two classes:

(1) Those designed to protect the circuit and apparatus both against short-circuit and against definite amounts of overload (e.g. fuses of the code which open on 25 per cent overload).

(2) Those designed to protect the system only against short-circuits; (e.g. expulsion fuses which blow at several times the current which they are designed to carry continuously). The line separating these two classes is not definitely fixed.

377. **Temperature.** — Coils or windings (such as accompany fuses of the magnetic blow-out type) should not exceed the limits set for machine coils having the same character of insulation. (See §§188 and 191.) The highest temperature for the fuse proper should not exceed the safe limit for the material employed (e.g. the temperature of the fiber tube of an enclosed fuse should not exceed the safe limit for this material, but an open-link metal fuse may be run at any temperature which will not injure the fuse material; except that no application of the above rule shall contravene the Code).

378. **Test.** — For fuses intended for use on circuits of small capacity, or in protected positions on systems of large capacity, see Code. For large power fuses intended for service similar to that required of circuit breakers, see §§370 to 374, or the Code as far as the latter applies.

LIGHTNING ARRESTERS

379. **Definition.** — A device for protecting circuits and apparatus against lightning or other abnormal potential rises of short duration.

380. **Rating.** — Arresters shall be rated by the voltage of circuit on which they are to be used.

Lightning arresters may be divided into two classes:

(a) Those intended to discharge for a very short time;

(b) Those intended to discharge for a period of several minutes.

381. **Performance and Tests.** Dielectric test same as §369.

The resistance of the arrester at double potential and also at normal potential, determined by observing the discharge currents through the arrester.

(c) In the case of any arrester using a gap, a test shall be made of the spark potential on either direct-current or 60-cycle a-c. excitation.

(d) The equivalent sphere gap under disruptive discharge shall also be measured, using a considerable quantity of electricity.

(e) The endurance of the arrester shall be tested to continuous surges.

PROTECTIVE REACTANCES

382. **Definition.** — A reactance for protecting circuits by limiting the current flow and localizing the disturbance under short-circuit conditions.

383. **Rating.**

(a) In kilovolt-amperes absorbed by normal current.

(b) By the normal current, frequency and line (delta) voltage for which the reactance is designed.

(c) By the current which the device is required to stand under short-circuit conditions.

384. **Performance and Tests.**

The Heat Test should be made with normal current and frequency applied until the temperature is constant. The temperature should not exceed the safe limits for the materials employed. See §§188 and 191.

385. **Dielectric Test.** — 2¼ times line voltage plus 2000, for one minute, from conductor to ground.

NOTE. — The reactance shall be so designed as to be capable of withstanding, without mechanical injury, rated current at normal frequency, suddenly applied.

RESISTOR OR RHEOSTAT

386. **Definition.** — Any device commonly known as a resistance used for operation or control. See Code.

INSTRUMENT TRANSFORMERS

387. **Definition.** — A transformer for use with measuring instruments, in which the conditions in the primary circuit as to current and pressure are represented with high numerical accuracy in the secondary circuit.

Under this heading and for more general use.

(a) A current transformer is a transformer designed for series connection in its primary circuit with the ratio of transformation appearing as a ratio of currents.

(b) A potential (voltage) transformer is a transformer designed for shunt or parallel connection in its primary circuit, with the ratio of transformation appearing as a ratio of potentials (voltages).

For further definitions relative to instrument transformers see §§111-114.

STANDARDS FOR ELECTRIC RAILWAYS

DEFINITIONS

388. **Transmission System.** — When the current generated for an electric railway is changed in kind or voltage, between the generator and the cars or locomotives, that portion of the conductor system carrying current of a kind

or voltage substantially different from that received by the cars or locomotives, constitutes the *transmission system.**

389. **Distribution System.**—That portion of the conductor system of an electric railway which carries current of the kind and voltage received by the cars or locomotives, constitutes the *distribution system.**

390. **Substation.**—A substation is a group of apparatus or machinery which receives current from a transmission system, changes its kind or voltage, and delivers it to a distribution system.

RATING OF SUBSTATION MACHINERY

391. **Nominal Rating of Substation Machinery.**—The nominal rating of a substation machine shall be the maximum output at 100 per cent power factor, which, having produced a constant temperature, may be increased 50 per cent for two hours without exceeding the standard ultimate temperature rise.

Substation machines shall be capable of carrying a load of twice their nominal rated load, for a period of five minutes, without disqualifying them for continued service. They shall also be capable of carrying a load of three times the nominal rated load for one minute. These overloads shall be applied after a continuous run at nominal rated load.

392. **Continuous Rating.**—The continuous rating of a substation machine shall be that load, at 100 per cent power factor, which it will carry continuously with a temperature rise not exceeding that set forth in §188, and fulfilling the other requirements set forth in these rules and summarized in §132.

CONDUCTOR AND RAIL SYSTEM

393. **Contact Conductors.**—That part of the distribution system other than the traffic rails, which is in immediate electrical contact with the circuits of the cars or locomotives, constitutes the contact conductors.

394. **Contact Rail.**—A rigid contact conductor.

395. **Overhead Contact Rail.**—A contact rail above the elevation of the maximum equipment line.†

396. **Third Rail.**—A contact conductor placed at either side of the track, the contact surface of which is a few inches above the level of the top of the track rails.

397. **Center Contact Rail.**—A contact conductor placed between the track rails, having its contact surface above the ground level.

398. **Underground Contact Rail.**—A contact conductor placed beneath the ground level.

399. **Gage of Third Rail.**—The distance, measured parallel to the plane of running rails, between the gage line of the nearer track rail and the inside gage line of the *contact surface* of the third rail.

400. **Elevation of Third Rail.**—The elevation of the contact-surface of the third rail, with respect to the plane of the tops of running rails.

* These definitions are identical in sense, although not in words, with those of the Interstate Commerce Commission, as given in their Classification of Accounts for Electric Railways.

† The contour which embraces cross sections of all rolling stock under all normal operating conditions.

401. **Standard Gage of Third Rails.**—The gage of third rails shall be not less than 26 inches (66 cm.) and not more than 27 inches (68.6 cm.).

402. **Standard Elevation of Third Rails.**—The elevation of third rails shall be not less than 2¾ inches (68.9 mm.) and not more than 3½ inches (89 mm.).

403. **Third-rail Protection.**—A guard for the purpose of preventing accidental contact with the third rail.

404. **Trolley Wire.**—A flexible contact conductor, customarily supported above the cars.

405. **Messenger Wire or Cable.**—A wire or cable running along with and supporting other wires, cables or contact conductors.

A primary messenger is directly attached to the supporting system. A secondary messenger is intermediate between a primary messenger and the wires, cables or contact conductors.

406. **Classes of Construction.**—Overhead trolley construction will be classed as *Direct Suspension* and *Messenger or Catenary Suspension*.

407. **Direct Suspension.**—All forms of overhead trolley construction in which the trolley wires are attached, by insulating devices, directly to the main supporting system.

408. **Messenger or Catenary Suspension.**—All forms of overhead trolley construction in which the trolley wires are attached, by suitable devices, to one or more messenger cables, which in turn may be carried either in *Simple Catenary*, i.e., by primary messengers, or in *Compound Catenary*, i.e., by secondary messengers.

409. **Supporting Systems** shall be classed as follows:

410. **Simple Cross-span Systems.**—Those systems having at each support a single flexible span across the track or tracks.

411. **Messenger Cross-span Systems.**—Those systems having at each support two or more flexible spans across the track or tracks, the upper span carrying part or all of the vertical load of the lower span.

412. **Bracket Systems.**—Those systems having at each support an arm or similar rigid member supported at only one side of the track or tracks.

413. **Bridge Systems.**—Those systems having at each support a rigid member supported at both sides of the track or tracks.

414. **Standard Height of Trolley Wire on Street and Interurban Railways.**—It is recommended that supporting structures shall be of such height that the lowest point of the trolley wire shall be at a height of 18 feet (5.5 m.) above the top of rail under conditions of maximum sag, unless local conditions prevent. On trackage operating electric and steam road equipment and at crossings over steam roads, it is recommended that the trolley wire shall be not less than 21 feet (6.4 m.) above the top of rail, under conditions of maximum sag.

RAILWAY MOTORS

RATING

415. **Nominal Rating.**—The nominal rating of a railway motor shall be the mechanical output at the car or locomotive axle, measured in kilowatts, which causes a rise of temperature above the surrounding air, by thermometer, not exceeding 90° C. at the commutator, and 75° C. at any other normally accessible part after one hour's continuous run at its rated voltage (and frequency

in the case of an alternating-current motor) on a stand with the motor covers arranged to secure maximum ventilation without external blower. The rise in temperature, as measured by resistance, shall not exceed 100° C.*

416. The statement of the nominal rating shall also include the corresponding voltage and armature speed.

417. **Continuous Rating.** — The continuous ratings of a railway motor shall be the inputs in amperes at which it may be operated continuously at ½, ¾ and full voltage respectively, without exceeding the specified temperature rises (see §420), when operated on stand test with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the volume of air on which the rating is based shall be given.

418. **Maximum Input.**—Railway motors shall be capable of carrying twice the current corresponding to their nominal rating for a period of five minutes, without flash-over or mechanical injury. They shall also be capable of carrying a load of three times their nominal rating for one minute under the same conditions. These overloads shall be applied when the motor is at the temperature which it would acquire when operating at its continuous rating.

TEMPERATURE LIMITATIONS

419. **The Allowable Temperature** in any part of a motor will be governed by the kind of material with which that part is insulated. In view of space limitations, and the cost of carrying dead weight on cars, it is considered good practice to operate railway motors for short periods at higher temperatures than would be advisable in stationary motors. The following temperatures are permissible:

TEMPERATURES

Class of material†	Maximum observable temperature of windings			
	Short periods		Continuous	
	By therm.	By resist.	By therm.	By resist.
*A*₁	100	125	85	110
B	115	145	100	130

* This definition differs from that in the 1911 edition of the Rules, principally by the substitution of a kilowatt rating for the horse-power rating and the omission of a reference to a room temperature of 25° C. The horse-power rating of a railway motor may, for practical purposes, be taken as 4/3 of the kilowatt rating. On account of the hitherto prevailing practice of expressing mechanical output in horse power, it is recommended that, for the present, the capacity be expressed both in kilowatts and in horse power, a double rating, namely,

kw.———————approx. equiv. h.p.———————

In order to lay stress upon the preferred future basis, it is desirable that on rating plates, the rating in kilowatts shall be shown in larger and more prominent characters than the capacity in horse power.

† See §188.

420. With a view to not exceeding the above temperature limitations the continuous ratings shall be based upon the *temperature rises* tabulated in the accompanying table:

TEMPERATURE RISES ON STAND TEST *

Class of material†	Temperature rises of windings	
	By thermometer	By resistance
A2	65	85
B	80	105

* The temperature rise in service may be very different from that on stand test. See §440 for relation between stand test and service temperatures, as affected by ventilation.

† See §188.

421. Field-control Motors.—The nominal and continuous ratings of field-control motors shall relate to their performance with the operating field which gives the maximum motor rating. Each section of the field windings shall be adequate to perform the service required of it, without exceeding the specified temperature rises.

CHARACTERISTIC CURVES

422. The Characteristic Curves of railway motors shall be plotted with the current as abscissas and the tractive effort, speed and efficiency as ordinates.

423. Characteristic Curves of Direct-current Motors shall be based upon full voltage, which shall be taken as 600 volts, or a multiple thereof.

424. In the Case of Field-control Motors, characteristic curves shall be given for all operating field connections.

EFFICIENCY AND LOSSES

425. The Efficiency of railway motors shall be deduced from a determination of the losses enumerated in §§426, 427, 429 and 430. (See also §§436 and 437.)

426. The Copper Loss shall be determined from resistance measurements corrected to 75° C.

427. The No-load Core-loss, Brush Friction, Bearing Friction and Windage shall be determined as a total under the following conditions:

In making the test, the kind of brushes and the brush pressure shall be the same as in commercial service. With the field separately excited, such a voltage shall be applied to the armature terminals as will give the same speed for any given field current as is obtained with the field current when operating at normal voltage under load. The sum of the losses above-mentioned, is equal to the product of the counter-electromotive force and the armature current. Under load, these losses shall be taken as follows [in accompanying table].

Per cent of nominal load	Loss as per cent of no-load losses
100 and over	130
75	120
50	115
25	110
15	100

428. In case it is desired to separate the core-loss from the other losses above described, this may be accomplished by measuring the power required to drive the motor at any given speed without gears, by running it as a series motor on low voltage and deducting this loss from the sum of the no-load losses at corresponding speed. (See §437.)

The core-losses at other loads shall be assumed as follows: At full continuous rated input 1.2 times no-load core-loss. At half continuous rated input 1.1 times no-load core-loss. The multipliers for other loads shall be in the same proportion.

429. **The Brush Contact Resistance Loss** to be used in determining the efficiency may be obtained by assuming that the sum of the drops at the contact surfaces of the positive and negative brushes is three volts.

430. The loss in single-reduction gearing and axle bearings varies with type, mechanical finish, age and lubrication. The following [accompanying] values, based on accumulated tests, shall be used in the comparison of motors:

LOSSES IN AXLE BEARINGS AND SINGLE-REDUCTION GEARINGS

Per cent of nominal rating	Losses as per cent of input
100 or over	3.0
75	3.5
50	4.5
25	6.0

ELECTRIC LOCOMOTIVES

431. **Rating.**—Locomotives shall be rated in terms of the adhesive weight, nominal one-hour tractive effort, continuous tractive effort and corresponding speeds.

432. **Adhesive Weight.**—The adhesive weight expressed in pounds shall be the sum of the weights on the drivers and of the drivers themselves.

433. **Nominal Tractive Effort.**—The nominal tractive effort, expressed in pounds, shall be that exerted when the motors are operating at their nominal (one-hour) rating.

434. **Continuous Tractive Effort.**—The continuous tractive effort, expressed in pounds, shall be that exerted when the motors are operating at their full-voltage continuous rating, as indicated in §417.

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for ½ or ¾ voltage, but in such cases the voltage shall be clearly specified.

435. **Speed.**—The rated speed, expressed in miles per hour, shall be that at which the continuous tractive effort is exerted.

APPENDIX I: RAILWAY MOTORS

436. In comparing projected motors and in case it is not possible or desirable to make tests to determine mechanical losses, the following values of these losses, determined from accumulated experience, will be found useful. They include axle-bearing losses, gear losses, armature-bearing losses, brush-friction losses and windage.

Per cent of nominal rating	Losses as per cent of input
150	5.0
125	5.0
100	5.0
75	5.0
60	5.3
50	6.5
40	8.8
30	13.3
25	17.0

437. The core-loss of railway motors is sometimes determined by separately exciting the field and driving the armature of the motor to be tested, by a separate motor having known losses and noting the differences in losses between

driving the motor light at various speeds and driving it with various field excitations.

The core-losses at other loads shall be assumed as follows:
At full continuous rated input 1.2 times no-load core-loss;
At half continuous rated input 1.1 times no-load core-loss.
The multiplier for other loads shall be in the same proportion.

438. **Selection of Motor for Specified Service.** — The following information relative to the service to be performed is required in order that an appropriate motor may be selected.

(a) Weight of total number of cars in train (in tons of 2000 lb.) exclusive of electrical equipment and load.
(b) Average weight of load and durations of same, and maximum weight of load and durations of same.
(c) Number of motor cars or locomotives in train, and number of trail cars in train.
(d) Diameter of driving wheels.
(e) Weight on driving wheels, exclusive of electrical equipment.
(f) Number of motors per motor car.
(g) Voltage at train with power on the motors — average, maximum and minimum.
(h) Rate of acceleration in m.p.h. per second.
(i) Rate of braking (retardation in m.p.h. per second).
(j) Speed limitations, if any (including slowdowns).
(k) Distances between stations.
(l) Duration of station stops.
(m) Schedule speed including station stops in m.p.h.
(n) Train resistance in pounds per ton of 2000 pounds at stated speeds.
(o) Moment of inertia of revolving parts, exclusive of electrical equipment.
(p) Profile and alignment of track.
(q) Distance coasted as a per cent of the distance between station stops.
(r) Time of layover at end of run, if any.

439. **Stand Test Method of Comparing Motor Capacity with Service Requirements.**—When it is not convenient to test motors under actual specific service conditions, recourse may be had to the following method of determining temperature rise.

440. The essential motor losses affecting temperatures in service are those in the motor windings, core and commutator. The mean service conditions may be expressed as a close approximation, in terms of that continuous current and core-loss which will produce the same losses and distribution of losses as the average in service.
